curve in the lumbar region. When the patient had to sit up he pulled himself up with his hands and kept his spine as stiff as possible. He had great difficulty in standing and assumed a characteristic attitude with his hands on his thighs. It was difficult to test any movement of the spine as the patient could not be induced to bend forwards or backwards, but lateral movements to the right seemed less than those to the left. Stooping was done with a stiff spine and on rising the patient "climbed his legs." On the day after admission Vidal's reaction was well marked. At times the patient complained of severe spasms in the muscles of the back. A spinal jacket was applied but seemed only to make the condition worse and large doses of sedatives had no effect on the pain. On July 10th the temperature, which had been normal since admission, rose to 102° F. The pain became more severe and there was marked rigidity of the muscles of the back. The knee-jerks could not be obtained. The fever continued in a rather irregular manner, the temperature varying from normal to 104°. On the 15th rose-spots were seen but the spleen could not be felt. The temperature became more regularly elevated, the tongue became furred, and the lips became dry. The patient lay with his knees drawn up and there were frequent spasmodic movements of the abdominal muscles. The area of splenic dulness increased. There was slight prominence of the spinous processes of the second, third, and fourth lumbar vertebrae, on each side of which there was some fulness. Over these areas the patient constantly complained of pain. On the 18th he was more comfortable and on the 29th the temperature became normal and there was little pain. On August 15th he could sit up in bed. He soon got up and was discharged on Sept. 8th with no deformity or tenderness but he could not bend forwards or backwards. He held his spine rigidly and still when he stooped "climbed down his thighs." A radiogram taken on July 5th showed on the right side between the second and third lumbar vertebrae a deposit of bone filling an intervertebral space, apparently deposited in the lateral ligament. In the three months following his discharge recovery progressed. He was able to run and to jump as well as ever but stiffness, lasting a few minutes, occurred in the lumbar region after remaining in the bent position for some time, which was evidently due to contraction of the muscles. The fever, which occurred six months after the original attack and four months after the onset of symptoms of "typhoid spine," might be regarded as due to the bone lesion or to a relapse or second attack of typhoid fever. Its duration of 19 days, the general appearance of the patient, the rose spots, and the increased splenic dulness point to the conclusion that it was a relapse or second attack. Professor McCrae also reports a case of spondylitis in paratyphoid fever in which radiography showed a deposit of new bone between the fourth and fifth lumbar vertebrae on both sides.

THE CHANGEABLE WEATHER.

It remains to be seen what will be the full effect on the public health and the death-rate of the recent sudden return to winter in the United Kingdom. If violent changes are as pernicious as they are generally supposed to be the returns of the Registrar-General during the next week or so will show a lamentable increase in the death-rate in all parts of these islands. Until Monday, Jan. 21st, the month had been mild, with an equable temperature and humid air. The thermometer rarely failed to rise to nearly 50° F. during the afternoon, frost was scarcely ever seen even on the ground and although the wind blew almost continuously from the south-west or the west there was extremely little rain. The change to winter commenced during Tuesday, when the drop of temperature during the day was all the more trying on account of the strong easterly wind by

THE method of treating syphilis by intramuscular injections of insoluble preparations of mercury in suspension has somewhat waned in popularity of late. A favourable account of the use of mercury salicylate is given by Dr. W. H. Palmer in the *Boston Medical and Surgical Journal*, 1906, No. 17. Mercury salicylate contains approximately 50 per cent. of mercury, it is insoluble in water, and is administered in suspension in liquid paraffin. The initial injection should contain half a grain of the salt or five minims of a 1 in 10 suspension. After two days a second injection of three-quarters of a grain is given and four days later the dose is increased to one and a quarter grains. Dr. Palmer has administered over 800 injections of the drug and in 75 per cent. of the cases a one and a quarter-grain dose given every seven days was sufficient to produce satisfactory results. In America it is customary to give a course of the injections for two years; after an interval of a few months the treatment is resumed for six months or a year. The liquid paraffin should be sterilised, otherwise painful *nodosities* may occur at the seat of injection. The needle should be sterilised by immersion in a mixture of alcohol and ether. The patient should lie face downwards, as in this position the gluteal muscles are more relaxed and in case of *syncope*, which may occur at the time of the initial injection, the position is a favourable one. The fluid is injected about 1 to 1½ inches below the surface, after which the seat of the injection is *massaged* for about 15 minutes to prevent the development of *nodosities*. Dr. Palmer considers that mercury salicylate has advantages over

all other preparations of mercury for intramuscular injection. When given by injection or by the mouth it does not produce gastric irritation, diarrhoea, colic, or other unfavourable symptoms, such as are produced by the other insoluble preparations of mercury. It very rarely produces abscesses and the nodosities that sometimes develop at the place of injection disappear within a few days without treatment. Owing to its slow conversion into a soluble form a considerable quantity of the drug can be injected at one time. Of the other preparations that have been employed perchloride of mercury is no more efficacious, causes much pain, produces abscesses, and the injections require to be repeated more frequently. Calomel and the yellow oxide of mercury both have the disadvantage of setting up a severe local reaction after injection. Dr. Palmer states that in rare instances unfavourable results have followed the employment of mercury salicylate, due to a pulmonary embolism produced by the introduction of the injection into the circulation when the needle penetrates a vein. Again, in about from 20 to 30 seconds after the injection the patient sometimes experiences a dry cough, accompanied by a sensation of tightness in the chest, faintness, nausea, and air hunger. The cough usually persists for some days, during which time the sputum may be tinged with blood.

FILTHY WOOL-FLOCK BEDS.

Mr. Peter Fyfe has contributed to the *Journal of the Royal Sanitary Institute* for January further evidence of the danger of common bedding to the public health. Four new wool-flock beds were bought in Bristol and Glasgow, at prices ranging from 7s. 6d. to 10s. 6d. each, and portions of the flock have been examined bacteriologically by Dr. R. M. Buchanan and chemically by Mr. F. W. Harris. The flock of the four beds contained respectively 3, 10½, 1, and 22 million organisms per gramme, comparing very badly with crude Glasgow sewage which contained about 197,000 organisms per gramme. A high proportion of soluble matter was present, the flock of one of the beds, weighing 33 pounds, losing 5½ pounds in weight when washed with 40 gallons of water. In all cases the washings on analysis compared unfavourably with crude Glasgow sewage. The latter absorbed 3.095 grains of oxygen per gallon in three minutes; the minimum corresponding figure for the washings from the flock bedding was 4.24 grains. The corresponding figure for each of the other three washings was more than double this amount. In each case the amount of albuminoid ammonia in the washings exceeded that present in crude sewage. Experiments were carried out to determine the effect on the atmosphere of a room of making an ordinary flock bed in a number of clean dwelling-houses. Agar culture plates were exposed in the rooms before and after the beds were made by the housewives in the usual way. Dr. Buchanan found an increase in the number of bacteria in the air of each apartment as the result of making the beds, the number being increased 30 times in the case of the cheapest bed and 239 times in the case of a bed which had been bought at second hand, while the atmosphere was rendered disagreeable in both apartments. The making of a number of more expensive beds produced only a relatively small increase in the number of organisms in the atmosphere and there was no perceptible odour or dust. As Mr. Fyfe points out, hundreds of thousands of persons in this country are constantly sleeping upon stuff which, after rinsing in a large volume of water, yields a liquid containing more putrescible organic matter than ordinary sewage, and more total solids, to say nothing of colour, than are allowed in effluents into rivers. Further, the presence of such filthy bedding in houses is a constant menace to the purity of foodstuffs, especially to milk, meat, and soup, for the storage of which there is

seldom proper accommodation in those houses in which cheap bedding is to be found. The bacteriological examination of the flocks has not yet been completed but sufficient evidence has been produced to demonstrate again the pressing urgency of legislative measures to prevent the continued sale of loathsome bed-stuffing.

THE VALUE OF SODIUM CITRATE IN DYSPEPSIA.

ACCORDING to Dr. L. Lachenay, writing in *La Semaine Médicale*, Nov. 7th, 1906, sodium citrate gives favourable results in the treatment of dyspepsia in adults, especially in cases of gastric pain, occurring three or four hours after a meal, followed by vomiting. He prescribes a 10 per cent. solution of the salt in tablespoonful doses (*cuillerées à soupe*), to be taken every five minutes from the time when the pain and sickness commence until they cease. The average dose required to give relief is from 30 to 60 grains; occasionally a dose of 15 grains will suffice, while in some cases it is necessary to give as much as 120 grains. In case of a relapse the treatment should be renewed, with the result that the symptoms frequently disappear in a few days. In 14 cases treated in this manner seven were cured in eight days; one patient, however, was under treatment for three weeks and two others for a month before a satisfactory result was obtained. The other patients were benefited by the treatment; one of these, suffering from ulcer of the stomach, experienced considerable amelioration of the pain from the administration of 45 grains of sodium citrate every day for 37 days.

THE RELATIVE SIZE OF THE MATERNAL PELVIS AND OF THE FŒTUS.

IN THE LANCET of Jan. 19th, p. 150, Captain J. C. Holdich Leicester, I.M.S., recorded the results of some observations on the above subject. He was led to an investigation of this matter by reading a paper by Captain Clayton A. Lane, I.M.S., published in THE LANCET of Sept. 26th, 1903, p. 885, entitled "A Clinical Comparison of the Maternal Pelvis and of the Fœtus in Europeans, Eurasians, and Bengalis." Captain Leicester's observations were carried out on the same class of women, only on a considerably larger scale. At the time of the appearance of Captain Lane's paper we considered the matter in a leading article and pointed out that the results obtained by him, which he ventured to enunciate in the form of a provisional law—namely, that "The child grows in utero in such a manner and at such a rate that at full term its size is proportional to that of the mother's pelvis through which it has to pass in order to be born," were not in accordance with the teaching of such authorities as La Torre, Badin, and Pinard, who had shown that the fœtus acquires the same development and size in contracted pelvises as in normal pelvises. The figures given by Captain Leicester are founded on a much larger series than those of Captain Lane—viz., on the measurements of 941 pelvises and 629 full term children. The conclusions at which he arrives are such as might be expected in this matter and differ considerably from those of Captain Lane. The well-known fact that the average interspinous and intercrural measurements bear no relation to the length of the conjugate diameter is clearly shown, but the figures quoted lend no confirmation to the result obtained by Captain Lane—namely, that as the conjugate diameter increases in size the percentage of the interspinous to the intercrural diameter shows a regular successive diminution. The influence of an increase in the admixture of native blood is shown in the size of the pelvis, thus the Bengali pelvis is the smallest, the East Indian next in size, the Eurasian next, and the European largest of all, with a regular gradation of size in

proportion to the degree of admixture of the native element, such as might be expected. The relationship between the size of the child as gauged by its weight and the size of the pelvis as gauged by the conjugate diameter which Captain Lane believed he had demonstrated by his measurements is not borne out in the results obtained by Captain Leicester, although it is true that his figures show some tendency in the same direction. In a further series of measurements the latter observer has endeavoured to estimate the size and weight of the children of various pregnancies passing through pelves with conjugate diameters of the same length. These results seem to confirm the well-known fact that the children of different pregnancies, even with the same mother, may vary very markedly in size. An investigation of this kind is of value in serving to confirm, although only in a very rough way, the results which have been obtained by the majority of investigators. We do not think that there is much to be gained by an endeavour to distinguish between such small differences as one-eighth of an inch in attempting to measure the conjugate diameter through the abdomen, the method practised by Captain Leicester, and not much reliance can be placed upon any such series of figures, numerous as they are, until they have been confirmed by a much larger series in which the measurements have been taken not by one but by several observers and then averaged. Captain Leicester's paper will be of service if it helps to expose the fallacy, only too common amongst medical writers, of attempting to found general laws upon quite inadequate data.

A LONDON CROWD ON THE ICE.

ANYONE who watched the crowd of skaters upon the Round Pond in Kensington Gardens upon the afternoon of Sunday, Jan. 27th, until the time when those in authority decided to clear the ice will have readily understood why the two terrible accidents which the middle-aged will recall as having happened in the Kensington Gardens before the Round Pond was made shallow and in Regent's Park were fraught with such loss of life. The incident which immediately preceded the ordering of all skaters to leave the ice was similar to others which had taken place earlier and served to demonstrate the recklessness which accompanies inexperience of danger, for probably few of those present either desired immersion or stayed to consider whether the water was shallow or deep. Something happened to attract attention—presumably a skater knocked one of his fellows over, or possibly fell through a hole, or otherwise became a centre of attraction—and immediately from all parts of the broad sheet of ice skaters and sliders, grown-up men and women, and children flocked together to see what had occurred, so that within a few seconds there were gathered in a dense crowd round a spot which for all they knew had just proved unsafe for one, or possibly for a group of their fellows, two or three hundred persons. Skating had not been permitted until the ice was strong enough to stand a strain which, no doubt, the keepers of the garden knew from experience would be likely to be put upon it, but we are inclined to think that the crowd was one which would have acted in a similar fashion had the ice been swaying and bending in every direction, with ten feet of water beneath it. We are inclined to believe also that foolishly as any crowd may behave when a few individuals set the example, those trained to country pursuits would hardly have acted in the same way as those used to the comparative safety of the ordinary Londoner's amusements. Our readers should recommend parents to warn their children against such behaviour on future occasions, for even with a thaw setting in a thorough wetting in icy water may do more than spoil clothes, and in a case of wholesale immersion, such as was likely to follow the scene described, children might

easily have fallen under others and have been placed in serious danger. Ice accidents, like boating accidents, have fatal endings before those around have time to realise what is going on, and no one can take up a newspaper when skating has begun without perceiving that the parent who shrinks from denying his child a transitory pleasure may have to reproach himself ever afterwards for his want of prudence or firmness.

THE CHALFONT COLONY FOR EPILEPTICS.

IN the year 1894 the National Society for Employment of Epileptics established the Chalfont Colony. The accommodation was then limited to 18 colonists but it has since grown to be a small village with a population of 200 epileptics. Even with this increase of accommodation the society has to refuse admission to a very large number of eligible persons who would undoubtedly benefit by the treatment were it only possible to house them. Up to the present time adults alone have been received into the colony but if only funds are forthcoming villas are to be built for the reception of epileptic children. The treatment in colonies of this kind is far superior to that which is possible in hospital, for in addition to the necessary medical supervision the patients are taught trades and other ways of earning a livelihood whereby they may become useful members of society. England is still far behind other countries in realising the value of the "colony" system for the treatment of such diseases as epilepsy and certain forms of mental enfeeblement. Nevertheless, experience has taught that they are institutions worthy of the most liberal support and it is to be hoped that the present appeal for the Chalfont Colony will meet with the success which it undoubtedly deserves. We note that contributions are to be sent to the honorary treasurer, Mr. H. Hamilton Hoare, or the secretary, Mr. G. Penn Gaskell, at the offices of the society, Denison House, Vauxhall Bridge-road, London, S.W.

MEMORIAL TO DR. FINLAYSON.

A LARGELY attended meeting of the medical profession and others interested was held in the hall of the Faculty of Physicians and Surgeons, 242, St. Vincent-street, Glasgow, on Jan. 24th, to consider a proposal to perpetuate the memory of the late Dr. James Finlayson who for many years occupied a foremost position in the medical world of Scotland. In the absence of the President of the Faculty, Dr. W. G. Dun, honorary treasurer of the Faculty of Physicians and Surgeons, was called to the chair. Amongst those present were the Lord Provost, Mr. John Wordie, Sir Hector C. Cameron, Professor R. Stockman, Professor S. Gemmell, Dr. D. Yellowlees, Dr. Alexander Robertson, Dr. J. O. Renton, Mr. H. E. Clark, and Dr. A. Freeland Fergus. The Lord Provost proposed, and Dr. Yellowlees seconded, a motion to the effect that a fund should be raised to perpetuate in some suitable manner the memory of Dr. James Finlayson, and this was adopted unanimously. At this stage Dr. Freeland Fergus made a statement to the effect that at a meeting of a few of Dr. Finlayson's professional friends held some little time ago it had been resolved to recommend the founding of a lectureship. The scheme recommended was briefly as follows. That a sum of money should be gathered together and a trust formed and that the trustees, whenever the accumulated interest permitted, were to appoint a lecturer to give one or more lectures in the west of Scotland and that the lectureship should be called the Finlayson Memorial Lectureship. In this way it would be possible to bring original workers and men of distinction from other places to give the practitioners in the west of Scotland an account of their researches and work.

The lecturer would not be chosen from any particular school or locality; he might be from abroad, or from London, or from Cambridge, or from anywhere else, the essential requisite being that he was a man of first rank as an investigator and that he was in a position to say something of practical value to practitioners. After some discussion it was moved by Mr. Clark and seconded by Dr. Renton that the memorial to Dr. Finlayson should take the form of a lectureship. This was unanimously agreed to and by a large majority it was further agreed that the lectureship should be on medicine and cognate subjects. Thereafter the meeting resolved itself into a general committee to carry out the scheme and an executive committee was elected with Sir Hector Cameron, convener; Mr. Robert Gourlay, LL.D., honorary treasurer, 124, St. Vincent-street, Glasgow; and Dr. Alexander Duncan, Faculty of Physicians and Surgeons, Glasgow, and Dr. Freeland Fergus, 22, Blythswood-square, Glasgow, honorary secretaries.

OVERHEAD WIRES ON TRAMWAYS.

AN action was heard recently before Sir William Selfe at the Brompton county court in which a jury awarded £50 damages to a plaintiff who claimed to have received personal injury through the falling of an overhead wire when travelling on the top of a tramway car. A wire, which undoubtedly fell, did not, according to his version of the occurrence, touch him but fell across the brass rail which ran round the car and with which he was in contact. The dispute in the case arose from the defendants positively denying that the wire which fell could have been a live one and calling their engineer to give evidence to this effect, and from their ascribing certain physical conditions of the plaintiff to his smoking to excess, supporting their contention by medical evidence, whereas medical witnesses for the plaintiff deposed that his symptoms were attributable to the shock which he stated that he had received. The shock itself was declared by the defence to be imaginary so far as electricity was concerned, and to have been due to fright. Whether the jury were right or wrong in their finding in this particular instance it seems clear that a county court jury is not the proper tribunal to weigh conflicting evidence of a scientific character. Such a case as that described could only be dealt with satisfactorily by a judge with the help of a medical assessor.

INTERNATIONAL CONFERENCE OF RED CROSS SOCIETIES.

THE Eighth International Conference of Red Cross Societies will be held in London from June 10th to 14th next, inclusive. The international conferences take place every five years, the last having been held at St. Petersburg in 1902. All Red Cross societies established in countries the Governments of which are signatory to the Geneva Convention are invited to send delegates to the Conference and many have already signified their intention of being represented. Invitations to send official delegates have been forwarded through the Foreign Office to the Governments of the countries in question. The Conjoint Board of the Royal College of Physicians of London and the Royal College of Surgeons of England has placed the Examination Hall, Victoria Embankment, at the disposal of the Conference. Field-Marshal Earl Roberts, K.G., V.C., will act as president of the Conference, and the following reception committee has been formed for the purpose of arranging a suitable programme of social functions for the entertainment of the delegates during the period of the Conference:—The Duchess of Montrose, the Marchioness of Lansdowne, the Marchioness of Londonderry, Georgiana Countess of Dudley, Lady Warrag.

Lord Rothschild, Viscount Escher, Viscount Iveagh, Lord Burton, Sir Ernest Cassel, Sir Frederick Treves, and Mr. A. K. Loyd. Provided that a sufficient number of exhibits are entered an exhibition of appliances in connexion with Red Cross work will be held at the same time as the Conference. The "Empress Marie Féodorovna prizes" will be awarded by an international jury for the best inventions tending to lessen the sufferings of sick and wounded soldiers. There are three prizes which will be given out of a sum arising from the interest on an investment of 100,000 roubles, the total amount available for the three 1907 prizes being about £2000. Full particulars of these competitions will be forwarded on application. The business arrangements of the Conference are being made by a committee composed of Mr. J. Danvers Power (chairman), Sir Frederick Treves, and Sir Benjamin Franklin, and all communications should be addressed to the secretary, British Red Cross Society, 9, Victoria-street, London, S.W.

CEREBRO-SPINAL FEVER.

AN outbreak of cerebro-spinal fever has apparently occurred in Belfast. Up to the time when the information reached us there had been 29 cases and 17 of these had proved fatal. Four children in one family were among the victims. Of these one went to bed on Wednesday, Jan. 23rd, apparently perfectly well, but became ill the next morning, death occurring very rapidly. The second child was attacked a little later and also died within an extremely short period. The two other children were similarly affected and died two days afterwards; the short period of illness was remarkable. From the information that we have had at present the cases would seem to be of the "type foudroyante" of French authors; in this country sometimes known as the "malignant type." The bacteriology of the disease has not been absolutely decided but the majority of observers consider that the diplococcus intracellularis meningitidis of Weichselbaum is the pathogenic organism, although this observer himself, reviewing the whole subject in 1903, concluded that it cannot be with certainty asserted that all epidemics are due to the meningococcus, but that some of them may be due to the pneumococcus. The ordinary methods of propagation of the disease are unknown and it has not been traced to food or water-supply. Isolation of affected persons is, of course, essential, but further experience and investigation will be necessary before the exact etiology of cerebro-spinal fever can be stated.

SHAKESPEARE'S "GYNÆCOLOGY."

TO Germany has spread our custom of complimenting Shakespeare on the possession of various kinds of expert knowledge. Under the heading "Shakespeare's Gynäkologie," Herr Franz von Winckel of Munich has recently published in the *Sammlung Klinischer Vorträge* an exhaustive study of the great dramatist's references to woman, especially in her sexual relations. Shakespeare, he avers, was practically a gynæcologist, but the numerous passages quoted to prove this assertion are not at all convincing from the modern scientific point of view. Thus from a passage in Part I. of *Henry the Sixth* Herr von Winckel infers that Shakespeare meant his hearers to believe that the sex of an unborn baby can be foretold from the character of the mother. A variant of this idea is expressed by Macbeth when he bids his lady to bring forth boys only, since she is made of stuff too stern to be the mother of the gentler sex. Falstaff is held to be a forerunner of Schenck and, in a speech in the Second Part of *Henry the Fourth*, is supposed to foretell the influence of a given diet upon the sex of the embryo. A water-drinker will be the father of "wenches" only. To the effects of

tright in the mother upon the health of the unborn Shakespeare makes frequent reference, as also to longings during pregnancy and kindred topics. But all this does not prove the great dramatist to have been in any sense a gynaecological expert, or even particularly learned in the current knowledge in such matters of his day. It proves, if anything, that he knew just as much as his fellow-burgurers of Stratford-on-Avon, who were doubtless well versed in such chap-book knowledge as is to be derived from the still popular pseudo-Aristotle's "Master-Piece." Great poets such as Shakespeare do not deal in paradox or specialism; they rather voice popular knowledge, superstitions, and errors in a melodious manner.

THE FOURTEENTH INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY.

THE preparations for the Fourteenth International Congress of Hygiene and Demography, which is to be held in Berlin from Sept. 23rd to the 29th, are well advanced. The subjects for discussion in the different sections have been definitely fixed and the openers of the discussion have been selected and invited to undertake the office. Their selection has been made in such a manner that the different questions can be treated from a wide point of view. The greater part of the openers of discussion of German nationality and a great many of those of foreign nationality have already accepted the invitations. All papers and other information referring to the congress can be obtained at the office of the Congress, Berlin, W, 9, Eichhornstrasse. The Secretary-General of the Congress is Dr. Nietner.

CLIFFORD v. TIMMS.

ON Jan. 26th Mr. Justice Warrington gave judgment in the above-mentioned case. The plaintiff and defendant had entered into a partnership as dentists under an agreement that if either partner should be guilty of professional misconduct the other partner should be at liberty to determine the partnership. The plaintiff's name was recently removed from the Dentists Register for infamous conduct in a professional respect and the defendant thereupon gave the plaintiff notice to terminate the partnership. The plaintiff now claimed a declaration that the notice was invalid and an injunction to restrain the defendant from acting upon it. Mr. Justice Warrington granted the plaintiff both declaration and injunction. This judgment being of great importance we shall deal with the matter at greater length in a future issue.

MEDICAL MEN AND SECRET COMMISSIONS.

IN a recent issue of the *Medical Times and Hospital Gazette* there is an article entitled "Doctors and Secret Commissions." In the course of this article we find these words: "An optician jeweller and silversmith stated that recently a man of scientific eminence in Scotland received very large commissions for recommending a certain make of microscope. It is an open secret that hospital doctors receive commissions from makers of surgical instruments." Thus it would appear that on the authority of an optician a statement has been made that hospital doctors receive commissions from surgical instrument makers. We draw attention to this statement because it has appeared in the public press several times within the last few years and we are still without confirmation of it. We have received a letter from one well-known firm of instrument makers, with reference to the article in our contemporary, in which the writer says that he "during an experience of just over 40 years has never met with a single instance of anything of the kind mentioned, and it would appear a curious circumstance that an optician should know more about our

trade than one actually engaged in it. I think that this unmerited aspersion on the honour of hospital surgeons should be refuted in your journal, and I think you may rely upon the statement which I offer." Refutation of vague accusations is always a difficult thing to compass and we thank our correspondent for his forcible advocacy of professional rectitude.

THE WINTER EXHIBITION AT BURLINGTON HOUSE

THE thirty-eighth winter exhibition of the Royal Academy of Art was opened to the public at Burlington House on Jan. 7th. The exhibition is of great interest and comprises pictures by early Flemish and Italian Masters, many fine examples of the Dutch School, and various paintings by deceased British artists. To come to two pictures which have a more purely medical interest, No. 64, by Teniers, is a wonderfully painted little picture entitled "The Quack Doctor." He is represented standing on a bench on which are various objects connected with his trade. He is holding up a bottle in his right hand which presumably contains some nostrum. No audience is in the picture but he is evidently haranguing a crowd. Another picture is a very finely painted portrait of Dr. William Pearce of Bath, by Gainsborough. Gainsborough, as is well known, used to go to Bath for his health and lived in the Clous. Pearce was an intimate friend of the artist and also of Miss Burr, the lady who became Mrs. Gainsborough. Contrary to what we believe is the usual custom for professional men in the eighteenth century, Dr. Pearce is habited in light-blue coat with lace ruffles. Among the other pictures which deserve special attention are No. 91, the well-known portrait of Miss Linley, by Gainsborough; No. 93, the magnificent portrait of Mrs. Lee Acton (Mr. Acton's second wife), by Romney; and No. 98, a portrait of Mr. Acton's first wife, also by Romney. An interesting picture is No. 52, entitled "A Picture Gallery," by Haecht. No. 113, "Burning of the Houses of Parliament," is a magnificent specimen of Turner's later manner; and of other pictures by Turner Sir Donald Currie lends the 25 little vignettes in water-colour to illustrate Campbell's poems. In the water-colour room are also shown sundry studies by Lord Leighton. Altogether the exhibition is one of extreme interest.

A MEETING of the Royal Sanitary Institute will be held in Stafford on Feb. 16th. A visit will be made to the Hanley sewage works at 11 A.M. and at 3 P.M. Dr. George Reid, county medical officer of health of Staffordshire, will open a discussion on the question, To What Extent must Authorities Purify Sewage? Those attending and wishing to be present at the lunch must notify the secretary of the institute not later than Feb. 9th.

THE Lettsomian lectures of the Medical Society of London for 1907 will be delivered by Dr. Charles E. Beever. Lecture I. is to be delivered on Feb. 4th, Lecture II. on Feb. 18th, and Lecture III. on March 4th. The hour of delivery is 9 P.M., and the subject of the lectures is the Diagnosis and Localisation of Cerebral Tumours.

THE King has given to Dr. Oliver Avison His Majesty's Royal licence and authority that he may accept and wear the Insignia of the Fourth Class of the Order of the Tai-Ken, conferred upon him by His Majesty the Emperor of Korea in recognition of valuable services rendered by him. Dr. Oliver Avison is an M.D. of Toronto.

At the meeting of the Incorporated Society of Medical Officers of Health on Feb. 8th there will be a discussion upon a paper to be read by Mr. H. O. Pilkington, medical officer

of health of Preston, entitled "The Reduction of Infantile Mortality without Municipal Milk Depôts."

THE annual meeting of the After-care Association will be held at the Apothecaries' Hall, Water-lane, E.C., on Tuesday, Feb. 5th, at 3 P.M. The chair will be taken by Mr. E. Parker Young, the Worshipful Master of the Society of Apothecaries.

THE Department of Public Health of Queensland reports that for the week ending Saturday, Dec. 22nd, 1906, 1 fatal case of bubonic plague occurred. The patient was a male, aged 21 years, who was employed as a hairdresser.

Mr. Henry T. Butlin, D.C.L., consulting surgeon to St. Bartholomew's Hospital, will deliver the Hunterian Oration at the Royal College of Surgeons of England on Thursday, Feb. 14th, at 4 P.M.

THE RÔLE OF THE BLOOD PLASMA IN DISEASE.

BY HARRY CAMPBELL, M.D., B.S. LOND., F.R.O.P. LOND.,
PHYSICIAN TO THE NORTH-WEST LONDON HOSPITAL AND TO THE
HOSPITAL FOR DISEASES OF THE NERVOUS SYSTEM,
WELBECK-STREET.

I.

THE human organism is made up of a vast congeries of cells, and its behaviour from the beginning to the end of life depends upon the inherent properties of these cells, and upon the outside influences which are brought to bear upon them. What are these influences? What, in other words, are the agencies which go to make up the individual cell-environments? They may be considered under two headings—the plasmic and the non-plasmic.

THE PLASMIC ENVIRONMENT OF THE CELLS.

All the cells of the body dwell, as did their remote unicellular ancestors, in a fluid saline medium.¹ This fluid—the tissue plasma or "lymph"—is derived from the blood, and, though it approximates in general character to blood plasma, its composition is peculiar for each kind of tissue, both because the capillaries of the different tissues yield different kinds of lymph and because every species of cell impresses its plasmic environment in a peculiar way.

According to Ludwig, whose views are forcibly supported by Starling, the lymph filters mechanically through the capillary wall, the quantity and quality of the filtrate being regulated by the amount of capillary blood pressure and the degree of capillary permeability. The greater the latter the more does the filtrating lymph approximate in composition to the blood plasma. Thus the highly permeable capillaries of the liver yield a lymph containing 8 per cent. of proteids and differing but little from the blood plasma, while the comparatively impermeable capillaries of the lower extremities exude a watery lymph containing no more than 4 per cent. of proteids.² Heldenheim, on the other hand, holds that the capillaries actually secrete the lymph by vital activity. What makes this view seem *a priori* probable is the consideration that the quality of lymph yielded by the capillaries could in this way be regulated with much greater nicety than by mere mechanical filtration; and, seeing that every species of cell has its own special lymph requirements, it surely would be of great advantage if each capillary were endowed with the power of secreting from the blood plasma just those ingredients, and those only, which are needed by the neighbouring cells, for in this case the latter would not need to

exercise any selection and their work would be correspondingly simplified.

The view that the quality of the exuding lymph is determined solely by mechanical means compels us to assume that the tissues are being constantly furnished with substances that they do not require, a conclusion which greatly complicates the problem of nutrition. Let me give a simple illustration. Certain substances are formed in the body for the purpose of influencing a limited group of cells. Such a one is *secretin*, the function of which is to excite the pancreas, and possibly also the liver, to specific forms of activity. Formed as it is in the duodenum it has, in order to reach these organs, to traverse the portal vessels, the pulmonary circuit, and the aorta, whence it is *dispersed throughout all the systemic capillaries*. Are we to suppose that this substance passes out of all these capillaries indifferently and is supplied in equal quantity to all the cells of the body—nervous, muscular, glandular, and the rest—when it is needed only by a limited number of them? It seems much more in accordance with the fitness of things that the capillaries of the pancreas and liver should exude it more abundantly than other capillaries. Is it possible that the pancreatic and hepatic cells attract secretin by chemiotaxis?³ Be this as it may, whatever the mechanism, or mechanisms, by which the passage of lymph through the capillary walls is regulated, whether by secretion, filtration, or chemiotaxis, singly or combined, one thing is certain: that mechanism, or those mechanisms, are not ideally perfect. Were the capillaries and surrounding cells endowed with perfect discrimination, so that only necessary ingredients were allowed to escape from the blood, it is clear that, except in the case of the excretory glands, no blood poison would ever be permitted to taint the extravascular plasma. This, as we know, is very far from being the case. A little thought, indeed, will show that the capillaries all over the body need to be permeable to poisons; for how otherwise could poisons engendered within the tissues be eliminated?

While, then, we must believe that discriminating agencies are at work regulating—imperfectly though it be—the quality of the lymph which the blood yields to the different tissues, we are probably right in assuming a tendency for all the constituents of the blood plasma, good, bad, and indifferent, to pass through the capillary walls, and in regarding the lymph of the body at large as having much the same composition as the blood plasma. We may, in fact, regard the two plasmas as kindred fluids, having their merits and defects in common, and we must assume that the slightest change in the one is reflected in the other, normal blood plasma thus meaning normal tissue plasma, abnormal blood plasma, abnormal tissue plasma, and *vice versa*. Whenever I use the unqualified term "plasma" it must be taken to mean either the blood or tissue plasma indifferently.

LOCAL PECULIARITIES IN PLASMA.

Though in general the plasma, and consequently the plasmic environment for individual cells, is much the same throughout the organism, yet local differences in it may exist sufficient to determine the occurrence of disease in some regions more than others. Apart from the fact that each variety of cell affects its environing plasma specifically, and apart from the fact that the bacterial invasion of a tissue causes a concentration of bacterial poisons in that tissue, local differences of plasmic constitution may occur as the result of local differences of circulation. It seems likely that a careful study of this subject would throw considerable light on the distribution of disease within the organism. Thus the blood-supply is more abundant in some tissues than others, and this tends to produce local variations in the character of the tissue plasma and in this way to determine the site of disease in particular areas. Those muscles, for example, which are most important to life, such as the heart and diaphragm, have a more abundant supply than other less important ones, and Ehrlich has shown that the distribution of vital staining is related to the degree of local blood-supply; thus in certain experiments with mice he found that the parts surrounding the central tendon of the diaphragm were more intensely stained than the peripheral portions, and he suggests that the distribution of paralysis in lead and arsenic poisoning may be explained on these lines.⁴ Similarly parts in which

¹ It is true that such cells as the superficial cells of the epidermis are not entirely surrounded by fluid, but these may be regarded as practically dead. All other surface cells, such as those of the serous and mucous membranes and of the cornea, have their free surfaces constantly bathed in fluid. Indeed, it may be said that no animal cell can maintain its vitality for any length of time unless entirely environed by fluid.

² "The cells of the capillary wall do not secrete tissue fluid. There is no evidence that they play any but a passive part in the formation and regulation of tissue fluid." (A. P. Reddard, *Some Recent Discoveries in Physiology*, edited by Leonard Hill, p. 617.) He holds that the tissue plasma is propelled out from the capillaries in obedience to osmotic, diffusive, and filtration.

³ In this connexion I may refer to the following quotation from A. P. Reddard. It seems likely that the living cells "institute the passage of nutriment from the blood to the tissue fluid, just as much as from the tissue fluid to themselves."—*Op. cit.*, p. 616.

⁴ *Studies in Immunity*, pp. 421 et seq.

the plasma is apt to stagnate are prone to disease. Sir William Gowers has argued that the arrangement of the veins opening into the superior longitudinal sinus is such as to predispose to venous stasis and consequent softening in this region from interruption of the intercellular plasmic flow; while Marie and Guillaumin have attributed the involvement of the posterior column of the cord in tabes to certain local peculiarities of the lymph circulation.⁵ Again, Sir Lauder Brunton suggests, and the suggestion is well worth consideration, that the absence, in subjects of high arterial tension, of the normal free expansion and contraction of the arteries may, by interfering with the due flow of lymph within their walls, predispose them to degeneration; and certainly the absence of rhythmic contractions in a muscle, and the consequent stagnation of plasma in its substance lead to its ultimate disorganisation.

There is possibly a further way by which local peculiarities in plasmic composition may be induced. Is it possible that when a parenchymatous cell (muscle, gland, or nerve cell) attracts a poison from the plasma, the damaged cell by the faulty metabolism thus ensuing affects its circumstant plasma injuriously, in such wise, e.g., as to irritate the local connective tissue? Can we in this way explain the otherwise puzzling fact that in genuine parenchymatous degenerations of toxic origin, the connective tissue in the neighbourhood of the affected parenchyma shows signs of irritation, while in other regions that tissue wholly escapes injury? Thus, in tabes dorsalis the pia mater over the posterior columns is thickened, and in granular kidney there is considerable induration of the renal capsules. When the poison causing the parenchymatous degeneration circulates freely all over the body, how comes it that, instead of causing a generalised fibrosis, it manifests a special tendency to set up fibrosis in the neighbourhood of those parenchymatous cells which specially attract it?

THE NON-PLASMIC ENVIRONMENT OF THE CELLS.

In the case of some cells, such as the blood corpuscles and connective tissue cells, the plasma constitutes the entire environment, but besides these plasmic influences most of the fixed cells of the body come under the direct influence of the nervous system; the human organism may, in fact, be regarded as consisting essentially of a nervous system having attached to the extremities of its efferent nerves—like so many leaves to the twigs of a tree—myriads of muscle and gland cells, all of which, in common with those of the nervous system itself, are held together by a connective-tissue framework, the whole being permeated by a complex vascular system containing blood and lymph. Thus it happens that nervous impulses are constantly flowing into the muscle and gland cells and influencing their activities; indeed, the very vitality of these cells—certainly of those of the voluntary muscular system, which constitutes no less than one half of the entire body weight—is dependent upon this constant inflow of nervous impulses, for when their motor nerve connexions are severed they disintegrate and die. And not only are muscle and gland cells directly influenced in this way by the nervous system, but contiguous nerve cells influence one another through their dendrites and axites, and in this way nerve impulses are enabled ceaselessly to reverberate throughout the entire nervous system.

In the case of the peripheral sensory neurons the non-plasmic environment embraces also those external agencies which operate upon the terminal expanses distributed to the organs of special sense, the integument, and the digestive tract. Such are the atmospheric and ether vibrations by which are produced the sensations of sound, heat, and light; such also are the grosser contacts which give rise to the sensations of touch, pain, and repletion. It is essentially these agencies which maintain the nervous system in that state of vibration by which it is agitated from the beginning to the end of life, and it is essentially through them, too, that a knowledge of the external world is gained and that the mental personality is gradually built up.

THE SOURCE OF THE BLOOD PLASMA.

The bulk of the blood plasma is made up of nutrient materials dissolved in water. These are derived from the food, and consist of the final products of digestion as poured by the hepatic veins and the thoracic duct into the general circulation. The ingested food first comes under the influence of the digestive juices, whereby the

proteids, saccharides, and fats are disintegrated; it then suffers a further change in its passage through the gastrointestinal epithelium; thereafter the whole of it, with the exception of a certain proportion of the fat (which travels by way of the lacteals), comes under the influence of the liver—which, putting the final touch upon the process of digestion, delivers into the general blood-stream fluid nutriment of a kind suitable for the nutrition of the tissues, be they the lowly elements of connective tissue or the more highly endowed cells of muscle, gland, or nerve.

We know very little concerning the changes which the liver effects in the plasma of the portal blood, but common sense, often more convincing than physiological experiment, points unmistakably to the conclusion that in the laboratory of this great gland the portal plasma undergoes its final preparation for entrance into the general blood-stream. Why, otherwise, should almost all the absorbed food be driven through this, the largest gland in the body, containing as it does much more glandular tissue than the entire digestive canal? Why, I say, should this occur, unless it be for the purpose indicated?

We may, I think, be sure that this digestive function is much the largest function, so to say, of the liver, for the glycogenic function, concerning which there is still great difference of opinion, may be regarded as only a part of the process of digestion (using this term in a comprehensive sense). The urea function, important though it be, might be carried on by a much smaller organ, seeing that its total daily output is less than a solitary ounce, and the biliary function again, by an organ no larger than the salivary glands, which yield as much saliva as the liver yields bile. In brief, we may safely conclude that at least three-fourths of the work done by the liver consists in preparing the portal plasma for entrance into the general blood-stream, a function which may be spoken of as "hepatic digestion," as distinguished from the "primary digestion," which takes place in the alimentary canal.

I have said that the bulk of the blood plasma consists of an aqueous solution of nutrient materials. But it may be asked, Why should it not contain as much waste as nutrient matter, seeing that in an individual whose weight remains stationary the daily quantities of each passing into the blood must be equal? In the case of the lymph environing the individual cells of the tissues it is probable that the two are on an average equal; but there can be little doubt that in health the blood contains a considerable excess of nutrient over waste material, and this must be because of the speedy elimination of the latter. How rapidly waste products are normally eliminated from the blood is shown by the rapid subsidence of dyspnoea in the well-trained athlete after, say, rowing the Henley mile.

But though the bulk of the solids of the blood plasma consists of nutrient materials elaborated by the digestive organs it would be a great mistake to think of the plasma as formed by any special organs or tissues, for in point of fact it is the product of the united activities of the tissues in general. Not a cell of the body but leaves its impress on this remarkable fluid, and that not merely in the sense of adding useless waste matter to it, but in the sense of providing it with constituents essential to the normal functioning of the tissues. Among the numerous substances thus produced are hormones, ferments, and antibodies.

The hormones are known to be produced by many different tissues, including the thyroid, thymus, adrenal, gastric, duodenal, pancreatic, ovarian, and testicular glands; and I shall presently argue that hormones are produced by all the tissues; certainly carbonic acid, a potent excitant of the respiratory centre, is. It is also probable that the plasmic ferments, which assuredly subserve some useful function, are produced outside the vascular system.

The fact that the blood plasma is elaborated by the tissues in general, and not by any special organs or tissues, is further shown by the phenomenon of antibody formation. We speak of the blood as forming these antibodies—antitoxins, antiferments, opsonins, bacteriolysins, precipitins, coagulins, and the rest—as though their elaboration were the function of the plasma itself; but the fact is that the power, the well-nigh limitless power, of producing antibodies belongs, not to the lifeless plasma, but to the living cells; and when we speak of the "memory of the blood" mean, not the memory of the lifeless plasma—a thing of the moment, undergoing ceaseless change—but of the tissues from which the antibodies are derived. What

⁵ See Dr. Ferrier's First Lumsden Lecture on *Tabes Dorsalis*, 1906.

these tissues are we do not certainly know, but it is probable that they include all the tissues of the body.

Inasmuch as the blood plasma is produced by all the cells in the body it follows that each single cell contributes to the plasmic environment of every other cell, and seeing that the activity of a cell is largely controlled by its plasmic environment it follows that all the remaining cells of the organism play some part in determining the activities of any particular cell. Observe that throughout life there take place a ceaseless action and reaction between the cells and the plasma, for, on the one hand, the activities of the cells determine the composition of the plasma, and, on the other hand, the composition of the plasma determines the activities of the cells.

THE COMPLEX CHEMICAL COMPOSITION OF THE BLOOD PLASMA.

These considerations regarding the source of the blood plasma show how subtly complex its chemical composition is. Indeed, as regards complexity of composition no fluid in nature can compare with plasma—be it that of the blood or the tissues. In thinking of the plasmic environment of individual cells let us ever bear this fact in mind. *Every active cell in the body is environed by a plasma containing a multitude of different chemical substances*, many of them of a highly complex constitution. These plasmic constituents may be grouped as follows: food-stuffs and free oxygen, ferments, hormones, anti-bodies, and excreta; and we shall best appreciate the highly complex nature of the plasma by inquiring—briefly though it must be—into the chemical composition of these various constituents. Such an inquiry brings into striking relief the meagreness of our knowledge regarding them. Most of them, indeed, defy the most delicate tests of the chemist.

Food-stuffs.—Even in regard to the nutritive constituents of the plasma—proteids, fats, saccharides, and salts—we have still much to learn. We have, it is true, a fairly accurate knowledge of the salts of the plasma, and we can estimate the percentage of serum albumin and serum globulin in this fluid, but our knowledge of the plasmic proteids is very incomplete. Our chemical knowledge of the plasmic fats and saccharides is equally limited; our ignorance of the former is shown by such a consideration as the following: when by means of exercise the weight of the body is reduced the stored fat is dissolved and carried to the muscles, there to be burnt off, and yet we are entirely ignorant as to the form in which it is conveyed.

Ferments.—Concerning the chemical composition of the ferments of the blood we know next to nothing; we are only able to judge of their presence by their power to induce fermentation.

Hormones.—The like is true of the numerous hormones which exist in the blood: we are all but entirely ignorant of their chemical composition. We know the composition of carbonic acid and of adrenalin, which can be now actually synthesised in the laboratory, but the analysis of the remaining hormones still baffles the chemist. To each of them we may apply Professor E. H. Starling's remarks concerning secretin: "We have no clue as to its chemical character." What chemist can detect the differences in respect of hormones between the blood of patients suffering respectively from exophthalmic goitre, myxedema, and Addison's disease, even though the hormonal defects in each of these affections may be such as profoundly to affect the metabolism of every cell in the body, to alter the individual in his entire being, and ultimately to compass his death? Where, again, is the chemist who can discover the hormonal differences, now known to exist, in the plasma of the menstruating and the non-menstruating, or the pregnant and the non-pregnant, woman?

We shall do well to reflect on this subject. The plasma contains numbers of these subtle essences, numbers of these mysterious messengers the function of which it is to incite the tissues to special forms of activity, and we are beginning to see how extensive is the rôle they play in health and disease. I venture to think that we shall have greatly to widen our conception of these remarkable substances, and that it will ultimately be found, as I suggested some years ago,¹ that many of the

products of cell activity, which we are wont to regard as merely useless or even harmful waste, serve a useful purpose. One of these purposes may be to stimulate the nervous system. It has long been known that the blood may from time to time contain waste products which depress nervous activity, but the possibility of certain waste products having normally an opposite stimulant effect has been lost sight of. That a waste product may act as a hormone is shown by the action of carbonic acid on the respiratory centre, which, as Starling suggests, may have evolved a special sensibility to this substance. This physiologist, indeed, hints that all the hormones may have been in the first instance waste products pure and simple. "We may, perhaps, assume that the more specialised messengers were at first accidental by-products of the selfish activity of the organ producing them, the first step in the development of a correlation being the acquisition of a sensibility to the substance in question by some distant organ."² It must not be forgotten that the waste products which are eliminated by the excretory glands have a hormonal action on those glands. In this sense such a substance as urea is hormonal as regards the kidneys, and by stimulating the renal epithelium to excretion may exercise a beneficial influence on it. Nay, we may go even further than this: the question may, I think, legitimately be raised whether the presence in the plasma in non-toxic proportions of cell excreta may not be beneficial to their vital activities. May it not be argued that cells which for myriads of generations have been bathed in plasma containing a large number of excretory substances, may have become so completely adapted to them that the complete absence of those substances from the plasma would be detrimental to cell activity? This view is rendered all the more probable from the fact that the tissues can to some extent adapt themselves to a decidedly toxic environment, so much so that a sudden removal of the toxic factor tends to a temporary lowering of function, as happens, for example, when the habitual opium-eater suddenly leaves off taking the drug.

The antibodies.—Though we generally attribute the presence of antibodies in the plasma to morbid conditions it is probable that they are also formed physiologically. In any case they are present in healthy blood, for after recovery from an infectious disease they persist, it may be for a long time, in the plasma. Concerning the chemical nature of these antibodies we know little or nothing.

Excreta.—Some may be inclined to think that, if our knowledge of the other constituents of the plasma is meagre, at least it is fairly complete concerning the excreta. Yet this is not the case. Two or three of these substances, such as carbonic acid, urea, and uric acid, have been satisfactorily analysed; but these are but a few among many. Numerous substances, concerning which we have no chemical knowledge whatever, are being continually eliminated by the lungs, skin, kidneys, and bowels.

Summary.—We must once for all rid ourselves of the notion that plasma consists simply of a few nutrient ingredients and useless excreta dissolved in water. We must, instead, think of it as an aqueous solution of an almost endless variety of substances, many of them possessing a highly complex composition and most of them defying the most careful and delicate methods of chemical research. And let us ever strive to keep clearly before us the fact that it is in a fluid of this kind that, from the beginning to the end of its career, every cell in the body lies bathed, and through it is subjected to an infinite variety of influences.

VARIABILITY OF NORMAL PLASMA.

The foregoing considerations by no means exhaust the subject of plasmic complexity. The composition of plasma differs normally in different races, in different individuals of the same race, and even in the same individual at different times. Each race—Caucasian, Mongol, and Negro—as well as every subrace of these races, every family—nay, every individual—has certain plasmic characteristics. No two humans, in fact, have exactly the same kind of plasma. Nor is this surprising, considering the exceedingly complex constitution of this fluid. These subtle individual differences do not, it is needless to say, admit of chemical demonstration. They can, however, be proved in a very simple way. There escape from the lungs, skin, and kidneys of every individual, numerous odiferous substances, which, coming as they do from the blood plasma, enable individual differences in plasmic composition to be detected during life by the sense of smell. We ourselves can detect some of the

¹ The convenient term "hormone" (from ὁρμή, I excite or arouse) has been suggested by Professor Starling, whose remarkable work with secretin on the subject of secretin has opened a new chapter in physiology.

² The Cravings for Stimulants, THE LANCET, Oct. 21st, 1903, p. 1001.

more decided of these differences, as those between the negro and the white man, and sometimes even between individuals of the same race; but certain animals, like the dog, have no difficulty in recognising the individual smell of anyone after quite a short acquaintance. A man's physical personality shows, indeed, as characteristically in his emanations and excretions as in his features and the conformation of his body.

And not only has every individual a plasmic constitution peculiar to himself, but one also which, as I have said, varies physiologically from time to time. Thus the plasma changes with every epoch of life, steadily altering through infancy, childhood, adolescence, maturity, and old age; and these changes determine, as we shall see, the functional and structural peculiarities of these successive epochs. Among other circumstances the composition of the plasma also varies with the season of the year, the time of day, with locality, climate, the nature and amount of food and drink consumed, and the amount of exercise taken. It is also considerably influenced by menstruation, pregnancy, and lactation. Just as individual plasmic differences can be detected by the sense of smell, so also can the differences met with in the one individual at different times, for these are all accompanied by characteristic emanations. We ourselves can sometimes detect these differences, though not generally until the limits of health have been passed.

VARIABILITY IN NORMAL METABOLISM.

Seeing that no two plasmas are the same in any two individuals, and that the metabolism of the cell must vary with the nature of its plasmic environment, it follows that no two individuals metabolise in exactly the same way. Seeing again that the plasma of any one individual varies considerably even in perfect health, it follows that his metabolism is normally subject to variation. In other words, the normal metabolism of man varies a billion-fold—a fact ever to be kept in mind. While recognising a fundamental plasmic and metabolic likeness between all, let us not forget these differences between individuals, and in the same individual at different times. Some of these metabolic differences are sufficiently obtrusive to be easily recognisable. Thus, some incline to fatness, others to leanness; some perspire readily, others with great difficulty; some are energetic, others lymphatic, and so on.

IMPORTANCE OF THE GLAND CELLS IN DETERMINING PLASMIC COMPOSITION AND METABOLISM.

The gland cells take precedence of all others in the elaboration of the plasma and in maintaining it in the normal condition, and consequently it is they more than any other cells which determine the character of the general metabolism—which strike, as it were, the metabolic note of the individual. It is they which elaborate the nutrient constituents of the plasma; it is they which furnish this fluid with all the recognised hormones (with the single exception of carbon dioxide); and they it is which purge the plasma of useless or harmful material. It may be, as I have suggested, that other cell types—e.g., muscle and nerve cells—yield the plasma substances which play a useful part in the economy; but even so they must be far inferior to the gland cells in their influence on the composition of this fluid. We must, therefore, assume that individual differences in the composition of the plasma, and in metabolism, depend chiefly upon differences in the vital activities of the glandular tissues. We cannot doubt that different individuals differ considerably in this latter respect, that marked individual differences obtain in the capacity of the gland cells to form such substances as pepsinogen and adrenalin, and that in some the gland cells elaborate substances different in character from those yielded by the corresponding gland cells in others. Doubtless similar differences obtain in regard to the biochemical activities of muscle and nerve cells, but one can hardly doubt that such differences are much less marked than in the case of the gland cells. One would expect the nature of the metabolism of nerve and muscle to be much the same in every one. While, however, the gland cells take precedence of all other cells in their influence on the composition of the plasma, and thus on the nature of metabolism, it must not be forgotten that the nervous system profoundly influences both the one and the other, not only through its direct connexion with the muscle and gland cells but indirectly through its control of the plasmic circulation.

MORBID PLASMA.

It is scarcely necessary to say that there is no sharp

line between normal and abnormal plasma; the one shades off imperceptibly into the other. There is, indeed, no such thing as an ideally normal plasma, for not only does the plasma vary, as we have just seen, for each individual, but for any given individual there are many grades of perfection—i.e., conditions of plasma consistent with what would generally be regarded as health.

It is not possible to deal adequately here with this enormous subject, concerning which our whole knowledge is but the veriest fraction—the merest fringe—of what is to be known. It must suffice to indicate some of the ways in which the plasma may be defective. The plasma may be faulty in respect of any of its normal constituents. It may, for example, contain too little or too much albumin, sugar, or fat, or these may exist in abnormal forms. Francis Hare contends with much force that an accumulation of carbonaceous material in the blood, a condition he terms *hyperpyramia*, is productive of many morbid results.¹ Or, again, there may be an excess, or deficiency, or perversion of the hormones or ferments normally present in the blood. Or, once more, there may be an accumulation of normal waste products. A second class of plasmic defects results from faulty metabolism, in consequence of which the plasma is poisoned by substances which do not properly belong to it. There are doubtless many such, though we as yet know very little about them. Such are *oboline* (found in the cerebro-spinal fluid of general paralytics) and its derivative *neurine*, also certain poisons met with in *uræmia* and *diabetic coma*.

The *toxæmia* of indigestion, or “*indigestion toxæmia*,” as we may conveniently term it, though it may often be largely due to bacterial poisons, results in the main from the absorption of the products of digestion—from what may be termed “*digestive metabolism*”—the substances thus formed being strictly *autogenetic*, which is not the case with bacterial poisons. Even in normal digestion albumoses, peptones, and other poisonous substances are abundantly formed, but these are either neutralised or are prevented from entering the blood stream as such by the gastro-intestinal epithelium and the liver. In indigestion such poisons may be formed in excess, and may successfully rush the two lines of defence and so contaminate the systemic plasma; and it is possible that weakness in these defences—e.g., from enteritis or hepatic disturbance—may have the same effect.

When we consider the infinite complexity of the digestive process in stomach, liver, and bowel, it is obvious that the opportunities for defective digestion are immense. And be it observed that there are innumerable different kinds of digestion—that no two individuals digest in the same way, that each individual digests differently at different times, that perfect digestion is an ideal seldom, if ever, attained; and that within the strict limits of what would by most be regarded as normal digestion there are innumerable grades of perfection, just as beyond those limits there are grades innumerable of imperfection. In an ideally perfect digestion the digestive products are delivered by the hepatic veins and the thoracic duct into the systemic blood stream, in the form most conducive to the normal metabolism of the tissues, and a little thought will convince the reader that there are myriads of ways in which this digestive output may show defect.

Last, but not least, the plasma may be contaminated by extraneous poisons—i.e., poisons either introduced as such from without (e.g., alcohol, nicotine, lead, tainted food) or formed within the body by bacterial agency. These bacterial poisons, which play so large and disastrous a part in disease, are yielded either by the bacteria themselves, or generated by a process of digestion which the bacteria set up in the plasmic proteids, in consequence of which albumoses, peptones, and kindred substances are produced.

Having regard then to the many individual respects in which the plasma may be faulty, and to the many different ways in which these various defects may be combined, it is no exaggeration to say that the varieties of defective plasma are, not many, but infinite.

Every disease, at least every general disease, is as it were mirrored in the plasma, though as yet we but rarely catch the reflection; but who can doubt that an all-wise physician might with very truth exclaim, “Show me the patient's plasma and I will tell you his disease.” And yet how little we know of the pathology of this subtly complex fluid—the arcanum of many pathological secrets, the repository of so many therapeutic indications. I have before me several

¹ Francis Hare, M.D.: *The Food Factor in Disease*.

be thoroughly boiled before being eaten; and (4) "untaugliches" flesh, that which must not be used for human food. The butcher is permitted to remove meat stamped as "tauglich," or quite healthy, to his shop and sell it freely to the public; all flesh bearing any other stamp must remain in the slaughter-house, the Berlin municipal officials being responsible for its further treatment and disposal. "Bedingt taugliches," or slightly diseased meat, is sterilised on the premises in large boilers and sold along with "minderwertiges," or poor meat, the former in its cooked and the latter in the raw condition, in an institution known as a "Freibank," which is attached to the slaughter-house. Such flesh is bought by the poorer classes, who come to the abattoir in order to obtain it.

Inspection.—All inspectors must be duly qualified veterinarians, having been specially trained in meat-inspection and having passed an examination on that subject as a test of their proficiency. They are divided into two classes, junior and senior, the former being much more numerous than the latter. It is the duty of the junior to go over and carefully to inspect every animal, in order to discover the presence or absence of disease. If the animals prove healthy then their carcasses and organs are stamped as "tauglich" or wholesome, and they may be removed by the butcher to whom they belong without further let or hindrance. Should disease of such a nature or degree be present as to prevent the junior from stamping them as "tauglich" then he pastes a label on their carcasses, bearing the words "preliminarily rejected and condemned, Dr. —, municipal veterinarian." The senior inspectors do not take part in the routine examination of every animal but confine their attention to those that are preliminarily rejected and condemned in order to determine whether they are diseased, and, if so, to what extent.

Mode of inspection followed by the junior inspector.—Slaughter has generally been in progress for some time before the junior comes on the scene. The slaughtered animals hang, cleaned and dressed, and cut into two through the vertebral column. The lungs, the heart, and the liver remain hanging to the carcass to which they belong by the trachea, which has not been entirely detached from the neck, so that the inspector may satisfy himself that they really belong to the animal in question. The heads, with the tongues attached, hang on hooks on the wall and all the organs belonging to each animal must be retained lest they should require to undergo examination or to be destroyed should the animal be condemned. A careful inspection of the following organs and parts is made. 1. The head. A general survey of the outer aspect (actinomycomata), lips, gums, and mouth (foot and mouth disease). The tongue is palpated (foot and mouth disease and actinomycosis); the latter is frequently found, generally in the form of a localised focus, which is merely cut out by the inspector, the rest of the organ being allowed to go free). The external and internal masticatory muscles are incised in such a manner as to expose their lymphatic glands which lie in that neighbourhood (cysticercus). The submaxillary, retro-pharyngeal, upper cervical and laryngeal glands are incised (tuberculosis, actinomycosis). 2. "Sling" (consisting of lungs, liver, and heart, all attached together, as removed from the animal). The lungs are carefully palpated and incised in a transverse direction (tubercle, inflammations, aspirations of blood, or stomach contents). The mediastinal and bronchial glands are incised (tubercle). The liver is inspected, palpated, and incised, along with the portal glands (degenerations, inflammations, tumours, tuberculosis, liver-flukes). The heart is incised in such a manner as to open into both chambers (endocarditis, degenerations, cysticercus, &c.). 3. The spleen is palpated and the splenic lymphatic glands are incised (tuberculosis, echinococci, &c.). 4. The mesentery. The glands are incised (tuberculosis). 5. The carcass. General aspect (hemorrhages, œdema, emaciation). Peritoneum and pleura (the diaphragm should be lifted lest it hang down and conceal something) (inflammations, tumours, tuberculosis). In the case of pleurisy in otherwise healthy animals the pleurae are carefully removed before the carcasses are stamped as "tauglich." 6. The sternum, the vertebral column, and the os pubis (tuberculosis, osteomyelitis). This concludes the examination made by the junior.

Mode of inspection followed by the senior inspector.—As already stated, the senior confines his attention to those animals preliminarily condemned by his junior colleague. These he subjects to a more thorough examination in order

to make up his mind if disease be present to any great extent, and if so whether the meat is to be entirely condemned and stamped as "untauglich" or unusable, or whether it may be possible for him to let it pass as "bedingt tauglich," in which case it is sterilised, or "minderwertig" (of poor quality), the two latter qualities being sold in the "Freibank." As tubercle is the disease from which animals are most frequently condemned a description of the mode of investigating such a case and the conclusions drawn therefrom may be given as an example. Two men who accompany the senior on his rounds attack the suspected carcass and mounting on ladders remove the following lymphatic glands, the one from the right, and the other from the left, half of the animal with the greatest dexterity, the process not occupying more than three minutes. 1. From the hind quarters.—External surface: (1) popliteal glands; and (2) kneefold glands. Internal surface: (1) superficial inguinal glands; (2) deep inguinal glands; and (3) internal iliac glands. 2. From the middle quarter.—Internal surface: (1) lumbar glands; and (2) renal glands. 3. From the fore-quarter.—External surface: prescapular glands. Internal surface: (1) lymphatic glands of inferior thoracic wall; (2) lymphatic glands of superior thoracic wall; and (3) upper, middle, and lower cervical glands. These glands are handed to the inspector, who, knife in hand, stands at a table and sections and examines them as they are brought. In the early stages of tubercle the glands become enlarged, and there is an increase in their fluid content; minute grey tubercles next make their appearance. Later the tubercles enlarge and become round in shape, while their centres show a cloudy appearance due to caseation, and finally a calcification takes the place of the caseation. Some of these calcified glands become greatly enlarged in size and so hard that they cannot be cut with a knife. It is very important that the inspector should be able to recognise the early stages of the disease, as, of course, glands which are beginning to enlarge and to exhibit minute tubercles are more dangerous than those in which calcification has already occurred. It is important to determine whether the disease is of a local or generalised character. Where extension has taken place through the lymphatics and not by means of the general circulation the tubercle is said to be local, whereas when the blood has conveyed the virus we speak of the condition as generalised. Generalised tubercle is of two forms: (1) acute, where the blood has become extensively infected by the bacilli and where in consequence we find many tubercles in nearly every organ; and (2) where there has been a slight infection of the blood with the formation of isolated tubercles in certain organs. It is interesting to note that it is the bases, and not the apices, of the lungs that first become affected with tubercle in bovine animals.

Professor Ostertag in the *Berlin Archives* says that the organs of cattle suffering from generalised tuberculosis are attacked in the following sequence. A uniform infection of the lungs and the liver, followed by an infection of the spleen and the kidneys, then the prescapular and the inguinal glands, the udder, the bones, and the joints. He also states that where the kneefold, the inguinal, the popliteal, the prescapular, and the axillary glands are tuberculous the bones of the extremities, the joints, and the skeletal muscles are also affected. Now it is taught that tubercle bacilli gain entrance into the muscular structures only when they are conveyed thither by the blood stream. Therefore the meat from animals suffering from generalised tuberculosis is injurious to health and must be condemned.

Much of the senior's inspection is merely confirmatory of that already undertaken by the junior. He should, however, prosecute his examination of organs and parts in a definite order: (1) meat, vertebral column, ribs, sternum, and pleura; (2) lymphatic glands (removed from carcass); (3) udder in female animals (palpation); (4) kidneys; (5) spleen (palpation, parallel longitudinal sections cut); (6) liver and portal lymphatic glands; (7) lungs, and adjoining glands; and (8) other internal organs. By proceeding thus, from the parts least likely to be affected to those that are generally diseased, he avoids, perhaps, selling healthy flesh by a knife already used to cut tuberculous material. Such an examination generally enables the inspector to decide without difficulty whether the disease is local or generalised.

Sanitary judgment.—If tubercle is present, even in isolated focus in any organ, the whole organ is to be condemned, as dangerous to health. Likewise, all appendages and lymphatic

small lymphatics running through it, or is the temperature which penetrates into the centre of a large roast of meat or other joint sufficient to effect the same purpose? Again, even if we grant that in the majority of cases the micro-organisms themselves are destroyed, we have yet to consider whether the toxins elaborated by their agency are affected by heat, and even if they are, whether their ingestion into the system is likely to prove injurious to health? Surely it is strange that in a country where meat is eaten twice, if not three times, a day by the majority of the inhabitants animals should still be permitted to be slaughtered in private abattoirs, situated often amidst the most insanitary surroundings and carried out without that degree of humanity, cleanliness, and precision which characterises the process in a country where all must be done under the eye of the skilled inspector.

THE REPORT OF THE MEDICAL OFFICER OF HEALTH OF THE ADMINISTRA- TIVE COUNTY OF LONDON.

II.¹

RESUMING our notice of this interesting report we observe that particular attention is devoted to an examination of the actual causes responsible for the sad waste of infant life which at an earlier stage of the report had been conclusively shown to persist in the metropolis. In a table contained in the report of the Committee on Physical Deterioration, to which frequent reference has been made in these columns, the infantile mortality in selected groups of English counties was compared in two quinquennial periods separated by an interval of 25 years. That table showed that in urban England throughout the quinquennium 1898-1902 infants died even more rapidly than in the period 1873-77, the maintenance of this high rate being especially due to excessive fatality from diarrhoeal diseases and from prematurity and congenital defects. In the report now before us a table for London is given showing the mortality in "trimesters" of the first half year of life in three quinquennia, commencing with the year 1888, when the deaths were first abstracted in periods of three months for the Registrar-General's reports. By this table the fact is established that whilst infantile mortality at ages under one year has increased since 1888 by nearly 1 per cent., it is in the first six months of life that the increase has been most conspicuous. As typical of what obtains in other London districts where the sanitary and social conditions are similar Sir Shirley F. Murphy quotes the case of St. Pancras, the medical officer of health of which borough has carefully analysed the present causes of infant mortality, comparing them with those that obtained in the same area a quarter of a century ago. In his recent annual report Dr. J. F. J. Sykes points out that so far from there having been improvement in recent years the infant mortality was slightly higher in 1901 than it had been in 1877. The death-rate from premature births and congenital defects in the earlier period was only about one-half that in the later, the mortality in 1901 being almost entirely confined to infants in the first week of life. Diarrhoeal diseases and diseases of the stomach and liver appear to have been more destructive in that year than in 1877 by about 50 per cent. In Dr. Sykes's opinion the statistics of St. Pancras indicate "that infants are dying at a younger and younger age, apparently from increased immaturity at birth, from diminished viability or capacity for survival, and from the increased prevalence of artificial feeding." Criticising the figures in the report of the Committee on Physical Deterioration, as well as those in the St. Pancras annual report, Sir Shirley Murphy is of opinion that the increases referred to in both cases may be apparent merely and may be due to natural causes. He thinks that better certification of deaths, especially those of children who survive their birth by a very brief period, would account for much of the apparent increase of mortality in early life from premature birth, &c. He further emphasises the well-known fact that diarrhoeal diseases are largely governed by temperature. With respect to this difference of

opinion between highly competent authorities, we would recall attention to what has already been shown in the present report—viz., that excessive infantile mortality is practically confined to the poor dwellers in overcrowded tenements. The facts are not before us, but we should regard it as highly probable that in their sufferings these luckless infants receive only a minimum of nursing or of medical care, the latter perhaps for only a few days or even hours before death. What proportion of these infants have been medically attended we know not, but from a cursory inspection of considerable samples of medical certificates relating to such cases we hesitate to base upon them any very definite conclusions on one side or the other.

With reference to artificial feeding and its well-known disastrous effects on infant health and life Sir Shirley Murphy quotes some interesting statistics prepared by Dr. W. J. Howarth, the medical officer of health of Derby, who has taken the trouble of analysing the causes of death of more than 8000 infants under one year of age and of recording in considerable detail their life-history. The figures show that, speaking generally and without reference to particular causes of death, hand-fed infants die in greater proportion than those who are fed first from the breast and afterwards by hand, and these again in greater proportion than those who are wholly breast-fed. The statistics of mortality from diarrhoea and epidemic enteritis are especially instructive, inasmuch as the numbers dealt with are sufficiently large to form a fair basis for calculation. From these we find that among 5278 breast-fed children only 86 died out of every 10,000 children born; among 1439 children first breast-fed and afterwards fed by hand, 216 died; whilst among 1626 exclusively hand-fed children not less than 517 died out of every 10,000 born.

Throughout London generally sanitary authorities and their officers are now devoting increased attention to the study and prevention of infantile mortality. In June, 1905, a conference was held at St. Pancras town hall under the presidency of Dr. R. M. Beaton, the present chairman of the public health committee. This conference was largely attended and resolutions were adopted which aimed at the bringing of newly born infants under the early supervision of the health authority, with a view of securing the better treatment and feeding of infants. In order to secure prompt information of the birth of infants female inspectors are employed by most of the London sanitary authorities and the Registrar-General has authorised the local registrars to supply these inspectors with the addresses of parents the births of whose infants have been registered. Moreover, the London County Council, as administrators of the recent Midwives Act, has arranged to receive from midwives weekly the names and addresses of patients attended by them and this information is forwarded to the medical officers of health concerned. From the fact that the returns received in this way are at the rate of about 30,000 births per annum, or about a quarter of the total births, the newly born infants in the poorest London districts will by this means be brought under supervision shortly after birth. The action hitherto taken by the sanitary authorities as a result of this information consists in the visitation of the mothers by female inspectors and the giving by them of printed and verbal advice as to the management and feeding of children. In Battersea, Lambeth, and Finsbury milk depôts have been provided either by the municipalities or by charitable effort, and in Holborn the borough council has made arrangements for the sale in suitable cases of wholesome milk for infant food at a reasonable cost to the parents.

Coming to the question of general mortality as it affects all ages of the population Sir Shirley Murphy provides the usual stereotyped tables and diagrams. In a preliminary table relating to the principal causes of death we note that the diseases showing excessive mortality in 1905 as compared with the decennial average are the following: pneumonia, cancer, and diseases of the urinary system; the remaining diseases, 17 in number, including those contributing most largely to the aggregate mortality, were in 1905 less fatal than the average. In another table the mortality in the several metropolitan boroughs is shown, the death-rates from certain diseases or groups of disease being given, after correction for deaths occurring in public institutions, and the deaths from cancer and pulmonary tuberculosis having been further corrected for age differences of population.

(To be concluded.)

¹ The first notice appeared in THE LANCET of Jan. 19th, 1907, p. 185.

ECONOMIC PROBLEMS IN THE PRACTICE OF MEDICINE.

DR. LAURISTON E. SHAW, President of the Marylebone division of the Metropolitan Counties branch of the British Medical Association, took the chair on Jan. 24th at a meeting held at the rooms of the Medical Society of London to discuss economic problems in the practice of medicine.

Dr. R. C. BUIST moved the following proposition:—

That the development of properly organized systems of mutual insurance for the costs of illness offers the most readily available method of reducing the admitted evils of excessive medical charity and the misuse of hospitals.

He said that so many people flocked to the great medical charities because they thought they were getting special skill at the hospitals that medical men must convince them that that skill was at their disposal by means other than by the abuse of the charities. For that purpose he suggested some system of insurance and the voluntary development of the principle seemed more practicable than the compulsory development of the plan. The provision offered by a voluntary system could be complete, including sick pay, medical attendance, and medicines. The essential conditions of satisfactory medical attendance were that the patient must be able to choose his medical man and that the remuneration to the latter must be adequate. Any such system must be based on the agreement of the whole profession. The work must be open to every practitioner who wished to do it and there must be local agreement as to the rates of remuneration for which the work must be done. He advocated the system called the Public Medical Service which was a local organisation undertaken by practitioners and served by all medical men who wished to take a part in the work. In those places where public medical service had been established the work was done economically and the patients had freedom to change their medical advisers if there was dissatisfaction.

Mr. H. W. ARMIT said that any properly organised system of insurance against the cost of sickness and accident which would apply to the mass of the population must be an enormous undertaking but would solve the problem if well conducted. The German system formed an excellent basis to work upon, even though it would not be wise to adopt it in its entirety in this country. All medical men should be prepared to take their share of the work at a reasonable rate of remuneration and all workmen earning less than £2 a week should be compelled to subscribe to the funds of the system. For the class of person earning from £110 to £300 a year no form of compulsory insurance was practicable. Workmen whose earnings are irregular would come under the Poor-law relief and those who spent their money in drink and other excesses could be dealt with in a penal way. The big insurance companies might be asked to issue policies to persons with incomes from £110 to £300 covering the charges made for medical attendance and for consultations with specialists when necessary. In such a scheme for each workman earning £2 a week a card would be issued and the medical practitioner would treat the patient according to contract and would receive payment from the institution insuring the workman. He contended that hospitals should only admit patients who produced their cards signed by the practitioner in charge of the case. No person whose income exceeded £300 per annum should be allowed to remain in hospital, except where it would be dangerous to remove the patient after first aid had been given. He thought that no voluntary insurance system for the lower wage-earner would meet with success. He suggested that the British Medical Association should prepare a Bill for compulsory insurance against sickness and accident.

Mrs. J. A. D. SCHARLIER, M.D., said that medical women must not be excluded from cooperation in any scheme suggested. Medical men and medical women must work together so that the whole profession would be able to do its duty to the poor of the country without undue pauperising and indiscriminate charity.

Dr. J. H. KEAY was disappointed with the position taken up by Dr. Buist. Dr. Keay did not consider that a scheme of optional insurance would meet the case. The time had gone by for relying upon anything but compulsory insurance.

Mr. G. GRUBBS said that actually there would be no difficulty in deciding what premiums were necessary in the case

of the different systems of insurance. Any national system would necessarily be more successful than an optional and partial one.

Sir HUGH BEEVOR sent a communication in which he said that the recent hospital conference recommended the provision of nursing homes, but he questioned whether nursing homes would be as efficient economically as hospitals. At first sight insurance seemed to be the most ready solution of the problem of hospital abuse, but he was not over-sanguine as to the possibility of this method of meeting the difficulty.

Dr. J. H. DAUBER said that the motion submitted appeared to him to be a counsel of perfection and he did not consider that the medical profession had any power to enforce it.

Mr. F. R. HUMPHREYS having addressed the meeting, Dr. R. BOXALL pointed out that the whole effectiveness of sick insurance depended on the system being properly organised.

Dr. BUIST having replied, the motion was put to the meeting and carried unanimously.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN 76 of the largest English towns 7874 births and 5584 deaths were registered during the week ending Jan. 26th. The annual rate of mortality, which had been equal to 22·4, 20·7, and 18·1 per 1000 in the three preceding weeks, rose again slightly to 18·2 in the week under notice. During the first four weeks of the current quarter the death-rate in these towns averaged 19·9 per 1000, the rate during the same period in London being 20·6. The lowest death-rates in the 76 towns during last week were 8·1 in Hornsey, 10·3 in Grimsby, 11·4 in Tynemouth, and 11·7 in Burton-on-Trent; the rates in the other towns ranged upwards to 25·6 in Hull and in Middlesbrough, 31·5 in Stockton, and 32·4 in Newport (Mon.). The 5584 deaths in the 76 towns showed an increase of 35 upon those returned in the previous week, and included 416 which were referred to the principal epidemic diseases, against 423 and 38 in the two preceding weeks; of these, 125 resulted from whooping-cough, 97 from measles, 80 from diphtheria, 45 from diarrhoea, 42 from scarlet fever, 25 from "fever" (principally enteric), and two from small-pox. The deaths from these epidemic diseases were equal to a mean annual rate of 1·4 per 1000 in the 76 towns; the rate in London from the same diseases did not exceed 1·1. No death from any of these epidemic diseases was registered last week in Sunderland, Gateshead, Wolverhampton, Northampton, or in nine other of the 76 towns; the annual death-rates therefrom, however, ranged upwards to 3·5 in Wigan, 4·6 in Walthamstow, 5·1 in Hull, and 6·1 in Middlesbrough. The 125 fatal cases of whooping-cough showed a further considerable increase upon recent weekly numbers, and caused an annual death rate of 1·7 in Willesden, 2·0 in Middlesbrough, 2·1 in Stockport, and 3·3 in Walthamstow. The deaths from measles, however, showed a further marked decline, although they caused rates of 1·8 in Wigan and in South Shields, and 3·5 in Hull. Diphtheria caused the largest proportional fatality in Derby, Berwick, Croydon, and Middlesbrough; scarlet fever in Newport (Mon.); and "fever" in Middlesbrough. The two fatal cases of small-pox occurred in Hull and in Cardiff. No case of small-pox has been under treatment in the Metropolitan Asylums Hospitals since the end of June last. The number of scarlet fever patients under treatment in the Metropolitan Asylums Hospitals and in the London Fever Hospital, which had steadily declined in the four preceding weeks from 3846 to 3405, had further fallen to 3291 at the end of the week under notice; 307 new cases were admitted to these hospitals during the week, against 285 and 325 in the two previous weeks. The deaths in London referred to pneumonia and other diseases of the respiratory organs, which had been 718, 620, and 446 in the three preceding weeks, rose again during the week under notice to 484, and exceeded the corrected average in the corresponding week of the last five years by 92. The causes of 53, or 0·9 per cent., of the deaths registered during the week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Leeds, Bristol, West Ham, Bradford, Newcastle-on-Tyne, Hull, Salford, and in 47 other of the 76 towns; the proportion of uncertified deaths, however, again showed marked excess in Birmingham, Liverpool, St. Helens, South Shields, and Gateshead.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in eight of the principal Scotch towns, which had been equal to 22·9, 20·8, and 20·5 per 1000 in the three preceding weeks, further declined to 19·1 in the week ending Jan. 26th, but exceeded the mean rate in the 76 English towns by 0·9. The rates in the eight Scotch towns ranged from 15·6 and 15·8 in Leith and Aberdeen, to 22·0 in Edinburgh and 26·9 in Perth. The 662 deaths in the eight towns showed a further decline of 51 from the numbers returned in the three preceding weeks, and included 71 which were referred to the principal epidemic diseases, against 67 and 80 in the two previous weeks. These 71 deaths were equal to an annual rate of 2·0 per 1000, which exceeded by 0·6 the rate from the same diseases in the 76 English towns; they included 25 which were referred to "fever," 16 to whooping-cough, 16 to diarrhoea, seven to scarlet fever, four to diphtheria, three to measles, and not one to small-pox. The 25 deaths from "fever" showed a further marked increase upon recent weekly numbers, and included 21 in Glasgow, two in Edinburgh, and one each in Leith and Greenock; 20 of the fatal cases in Glasgow as well as the three returned in Edinburgh and Greenock were certified as cerebro-spinal meningitis. Of the 16 fatal cases of whooping-cough, showing a decline from recent weekly numbers, 11 occurred in Glasgow, and four in Aberdeen; and ten of the deaths referred to diarrhoea were returned in Glasgow. Three deaths from scarlet fever occurred both in Glasgow and Edinburgh, two from measles in Edinburgh; and two from diphtheria in Dundee. The deaths in the eight towns referred to diseases of the respiratory organs, including pneumonia, which had been 185 and 177 in the two preceding weeks, further declined to 134 in the week under notice, but exceeded the number returned in the corresponding week of last year by 24. The causes of 33, or 5·0 per cent., of the deaths registered during the week in the eight towns were not certified or not stated; the mean proportion of uncertified deaths in the 76 English towns during the same week did not exceed 0·9 per cent.

HEALTH OF DUBLIN.

The annual death-rate in Dublin, which had been equal to 31·9, 29·0, and 27·5 per 1000 in the three preceding weeks, rose again to 28·6 in the week ending Jan. 26th. During the first four weeks of the current quarter the death-rate in the city averaged 29·2 per 1000, the mean rate during the same period being only 20·6 in London and 21·3 in Edinburgh. The 214 deaths of Dublin residents during the week under notice showed an increase of eight upon the number in the previous week, and included seven which were referred to the principal epidemic diseases, against eight and 11 in the two preceding weeks. These seven deaths were equal to an annual rate of 0·9 per 1000, and included five from whooping-cough, one each from "fever," and scarlet fever, and not one either from diphtheria, measles, diarrhoea, or small-pox. The five fatal cases of whooping-cough corresponded with the number in the previous week. Six inquest cases and seven deaths from violence were registered during the week; and 80, or 42·1 per cent., of the deaths occurred in public institutions. The causes of four, or 1·9 per cent., of the deaths registered in the city during the week were not certified; the percentage of uncertified deaths in the week under notice was equal to 7·9 in Edinburgh, while in London all but one of the 1647 deaths were duly certified.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

THE following appointments are notified:—Staff Surgeon: A. H. Jeremy to the *Fox*, temporary, on recommissioning. Surgeons: H. B. Hill to the *Victory* for Physical Training School, G. D. Walsh to the *Hampshire*, and G. H. S. Milln to the *Halcyon*.

ROYAL ARMY MEDICAL CORPS.

Colonel J. J. Morris, administrative medical officer, Portsmouth Coast Defences, is granted leave of absence from Feb. 1st to April 9th next. His duties will be carried out by Lieutenant-Colonel W. G. A. Bedford, C.M.G. Major O. J. Healy, from Ceylon is appointed for duty at Londonderry. Captain B. S. Bartlett, from India, is posted to the Eastern

Command for duty. Lieutenant G. F. Rugg is posted to the Eastern Command.

ROYAL ARMY MEDICAL CORPS IN INDIA.

The following appointments have been made:—Lieutenant-Colonel D. O'Sullivan, to command the Station Hospital, Secunderabad; Lieutenant-Colonel T. J. R. Lucas, O.B., to command the Station Hospital, Bangalore; Major H. S. Peeke, to command the Station Hospital, Campbellpore; Major D. Shiell, to command the Station Hospital, Dinapore; Major M. Boyle, to Station Hospital, Bareilly, for duty; Captain A. O'B. Wroughton, to command Station Hospital, Malapuram; Lieutenant W. O. Nimmo, to Station Hospital, Fyzabad, for duty on completion of course of instructions in sanitation at Lucknow; and Lieutenant M. Keane, to Meerut on completion of course of instructions in sanitation at Lucknow.

The undermentioned officers, on arrival from England, are posted as follows: Lieutenant-Colonel H. S. McGill to 6th (Poona) Division; Lieutenant-Colonel R. L. R. Macleod to 4th (Quetta) Division; Lieutenant-Colonel H. P. G. Elkington to 5th (Mhow) Division; Lieutenant-Colonel J. J. O'Donnell to 5th (Mhow) Division; Major F. W. Begbie to 5th (Mhow) Division; and Captain H. G. Martin to 6th (Poona) Division.

INDIAN MEDICAL SERVICE.

The King has approved of the following promotions made by the Government of India. Lieutenants to be Captains (dated August 31st, 1906): Robert Kelsall, John Hay Burgess, Charles Hildred Brodrick, John McCallum Anderson Macmillan, Olifford Allchin Gill, William Edward James Tuohy, Terence Francis Owens, Richard Francis Steel, George Francis Innes Harkness, Arthur Charles Ingram, Gordon William Maconachie, Ernest William Charles Bradfield, Alexander William Montgomery Harvey, Charles Isherwood Brierley, John Brown Dalzell Hunter, and Edward Temple Harris.

ARMY MEDICAL RESERVE OF OFFICERS.

The undermentioned Surgeon-Lieutenant-Colonels having resigned their commissions in the Volunteers cease to belong to the Army Medical Reserve of Officers:—George England and Joseph Willoughby Hodgson.

IMPERIAL YEOMANRY.

Hampshire (Carabiniers): Surgeon-Lieutenant H. A. Ahrens to be Surgeon-Captain (dated Nov. 28th, 1906). *Montgomeryshire*: Surgeon-Lieutenant H. Connop resigns his commission (dated Dec. 1st, 1906).

VOLUNTEER CORPS.

Rifle: 2nd Volunteer Battalion, the East Surrey Regiment: Surgeon-Lieutenant-Colonel and Honorary Surgeon-Colonel W. Gandy is borne as supernumerary whilst holding the appointment of Brigade Surgeon-Lieutenant-Colonel, Senior Medical Officer, East Surrey Volunteer Infantry Brigade (dated June 1st, 1906). 1st Volunteer Battalion, the Royal Sussex Regiment: Surgeon-Lieutenant H. V. Pryce resigns his commission (dated Jan. 1st, 1907). 5th (Glasgow Highland) Volunteer Battalion, the Highland Light Infantry: Surgeon-Lieutenant-Colonel A. Mappee is granted the honorary rank of Surgeon-Colonel and resigns his commission, with permission to retain his rank and to wear the prescribed uniform (dated Dec. 29th, 1906).

Royal Garrison Artillery (Volunteers): 1st Edinburgh (City): Surgeon-Captain R. B. Parves resigns his commission (dated Dec. 21st, 1906). 1st Kent: Surgeon-Lieutenant-Colonel O. Arrol is granted the honorary rank of Surgeon-Colonel (dated Jan. 1st, 1907).

Royal Engineers (Volunteers): 2nd Lanarkshire: Surgeon-Lieutenant J. A. Cook resigns his commission (dated Dec. 13th, 1906). 1st (Sheffield) Yorkshire (West Riding): Surgeon-Major O. H. Willey is granted the honorary rank of Surgeon-Lieutenant-Colonel (dated Dec. 30th, 1906). Surgeon-Major and Honorary Surgeon-Lieutenant-Colonel C. H. Willey resigns his commission, with permission to retain his rank and to wear the prescribed uniform (dated Dec. 31st, 1906).

ROYAL ARMY MEDICAL CORPS (VOLUNTEERS).

Cheshire Bearer Company: Surgeon-Major George William Sidebotham, from the 4th Volunteer Battalion, the Cheshire Regiment, to be Major (dated Dec. 1st, 1906). East Surrey Bearer Company: John Alexander Preston, gentleman, to be Lieutenant (dated Dec. 8th, 1906).

ROYAL ARMY MEDICAL CORPS EXAMINATION.

The following is the list of successful candidates for commissions in the Royal Army Medical Corps at the recent examination in London for which 78 candidates entered, of the successful 30 candidates 14 were university graduates:—

Names.	Marks.	Names.	Marks.
W. R. Beaman ...	612	J. H. Garley ...	503
C. Cassidy ...	530	F. H. M. Chapman ...	507
A. D. Fraser ...	575	A. C. Elliott ...	503
M. P. Leahy ...	565	J. du P. Langrishe ...	503
F. T. Turner ...	555	W. G. Arvis ...	500
A. I. Fortescue ...	550	W. B. Pardon ...	497
H. G. Gibson ...	548	H. M. J. Perry ...	495
J. L. Wood ...	545	J. C. Hart ...	493
S. Field ...	533	M. O. Wilson ...	493
R. D. O'Connor ...	533	T. H. Scott ...	491
M. F. Mackenzie ...	523	L. A. A. Andrews ...	489

O. R. McEwen ...	510	F. Carement ...	479

ENTERIC FEVER IN INDIA.

The following subjects were discussed at the second meeting of the standing committee on enteric fever recently held at Simla, and resolutions passed concerning them—viz., removal and disposal of sewage, washing of clothes, appointment of special sanitary officers for large cantonments, organising regimental supervision of sanitation in lines, improved means for removing infected clothing from barracks to hospitals for disinfection, disinfectors for excreta, the provision of heat-exchange water purifiers for use in camps and on service, means of conveying meals from kitchens to barrack rooms, increasing the number of clinical laboratories at divisional and brigade headquarters.

It is satisfactory to be able to record a considerable and progressive decrease in the cases of enteric fever occurring recently amongst British troops, the fresh admissions under this heading throughout the whole of India being for the last three months as follows: September, 117; October, 66; November, 31. No doubt the increased attention paid by the authorities to sanitation has already contributed to this reduction.

JOURNAL OF THE ROYAL ARMY MEDICAL CORPS.

The January number of this journal contains many papers on a variety of subjects of more or less special interest to officers of the medical services, dealing as they do with sanitation in India, enteric fever, malaria, and diseases of hot climates, together with those incidental to life in the public services. The first article, by Major F. Smith, D.S.O., R.A.M.C., is on the Soldier's Heart and the Civilian's. The liability of the soldier to acquire an increased pulse-rate and palpitation has been often remarked upon and described under such titles as "irritable heart," the "trotting heart," &c. But as the result of an experimental comparison conducted on a limited scale Major Smith is led to conclude that the soldiers' hearts do not beat more rapidly than civilians' hearts, that the influences operating on soldiers are also operating on those of civilians, and he thinks that some valuable information might be gained by a more extended examination and inquiry into the subject. Colonel Francis J. Lambkin, R.A.M.C., has a report on "So-called Virulent Syphilis and its Treatment." This number also contains some good and discriminating reviews.

ADMINISTRATIVE MEDICAL OFFICERS.

The *Broad Arrow* states that the Army Council has decided that administrative medical officers shall in future have such administrative medical charge and authority as regards their areas as is now vested in principal medical officers. Administrative medical officers and senior medical officers of the larger stations will, before submission to higher authority, bring such questions to the notice of local commanders, in order that the latter may have an opportunity of expressing their opinions thereon.

SWANSEA GENERAL HOSPITAL.—At a meeting of the Swansea hospital board held on Jan. 22nd a resolution passed by the local branch of the British Medical Association was read. It stated that in consequence of the increasing abuse of the hospital as a charity organisation the Association urged the appointment of a special officer to investigate the circumstances of all applicants for treatment before they are seen by the medical staff. After some discussion it was decided to refer the matter to the house committee of the institution.

Correspondence.

"Audi alteram partem."

THE HOSPITAL FUNDS AND THE MEDICAL PROFESSION.

To the Editors of THE LANCET.

SIRS,—All friends of the voluntary hospital system are grateful to you for the constant help and encouragement you give to the great hospital funds which promise to be saving of our voluntary hospitals. This gratitude will only be increased by your leader of Saturday last on the steps taken by the King's Fund and the Hospital Sunday Fund respectively to place their constitution on a more permanent and satisfactory basis. Such a step on their part is the more reasonable from their increasing importance and the many indications of public confidence. Such confidence is a great treasure and cannot be too jealously guarded. One of its advantages is that it permits a candid criticism of both funds and of all doubtful or exceptional proposals. I ask leave to say two or three words on your loyal and friendly criticism.

First, in regard to Section 3 of the Bill providing for the management of the King's Fund and putting all power over the general council and the committees, over the monies collected and over their distribution into the hands of the Sovereign or, through him, those of the Heir Apparent. It will be astounding news to the profession and the public that such a proposal should be made in Great Britain, in a country which boasts of its voluntary hospitals and which rejoices in a king and heir so splendidly loyal to the constitutional principles which underlie all public finance, especially monies supplied on the voluntary principle. If free and unhampered discretion is not allowed to, or is not used by, those in the management who are supposed to represent the public, it may well be feared that the delicate system of voluntary institutions will be fatally impaired and that on the King or his Heir will fall all the blame. Doubtless we are in some degree spoiled by having such a King and Heir Apparent as at present. And we cannot doubt that the Council of the King's Fund—for we could never blame His Majesty or His Royal Highness the Prince for this remarkable proposal—have been misled by the subtle influence of this fact. Nevertheless, they must be reminded of their duties and cannot be excused for sinking their responsibilities as trustees of funds the scale of which is undoubtedly largely due to the benevolent and kindly nature of the Sovereign's interest in this great charity. Neither the King nor the British public will think the less of them for modifying or withdrawing a clause which shocks every principle of hospital or public finance.

Your reference to the action of the metropolitan branch of the British Medical Association and the Hospital Sunday Fund will, I am sure, be taken in good part by this Fund. But I am not so sure that the branch is so much aggrieved as it would have the public and the profession think. Certainly it has no such grievance as to justify it in opposing before the Privy Council the grant of a charter to the Hospital Sunday Fund on the ground of non-representation of the medical profession on the Fund. It is by more genial and friendly methods than this that the branch is likely to effect its objects. The objectors write as if the medical profession had no representative on the Fund. It may surprise the profession to know that Sir William Church, Mr. Bryant, Sir Dyce Duckworth, Mr. Willett, Sir Frederick Treves, Sir Stephen Mackenzie, and Mr. Pearce Gould are on the Hospital Sunday Fund, to say nothing of general practitioners, two of whom are on the Fund. Not only so. It is within my knowledge that the offer of a seat on the council has been made at least once to another general practitioner, highly respected and of much weight in the council of the British Medical Association and of the metropolitan branch thereof. Further, let me say that Sir William Church is a member of the distribution committee, if not chairman, and that Sir William Church was chosen very lately to preside over a very special and important meeting of the British Medical Association. I should be, of course, delighted to see more general practitioners on the council and this can easily be arranged through the action of the churches of London which contribute the money.

Under these circumstances, Sirs, I think you will agree

that the British Medical Association is rather apt at the creation of grievances and that the Hospital Sunday Fund might expect a little different treatment at its hands.

I am, Sirs, yours faithfully,
Highbury-place, N., Jan. 29th, 1906. JAMES GREY GLOVER.

THE DISCOVERER OF THE ETIOLOGY OF PUERPERAL FEVER.

To the Editors of THE LANCET.

SIRS,—Will you kindly grant me space for a few remarks on the question of the discovery of the etiology of puerperal fever and the claims of priority advanced on behalf of Oliver Wendell Holmes and of Semmelweis? I only wish to state certain conclusions the truth of which I hope soon to demonstrate to all unprejudiced readers of the history of medicine. There can be no real question of priority. Holmes did good service to obstetrics and consequently to humanity, but he discovered nothing; he added nothing to the sum of the scientific knowledge of obstetrics by his essay on "The Contagiousness of Puerperal Fever." Semmelweis, on the other hand, discovered the true cause of puerperal fever; he laid the scientific basis of our prophylaxis and so rendered a service to humanity comparable only with that of Jenner. Moreover, he devoted the whole of his too brief span of life to the spread of his doctrine (*Lehre*), and he lived long enough to put an end to the worst ravages of puerperal fever in the lying-in hospitals of Europe, for many, who openly jeered at his fanaticism and his eccentricities, privately applied his principles to the prevention of the disease in their own institutions. They gave their patients the benefit of the doubt.

Holmes collected evidence from the practical experience of other men, for he had comparatively little practical experience of his own, and, in some measure like a barrister, he marshalled this evidence and stated his conclusions in an essay of which the most striking feature is its extraordinary literary charm, at least in the estimation of those who are attracted by his style. Holmes entered upon his inquiry with the preconception which he held in common with most of his contemporaries that: "The disease known as puerperal fever is so far contagious as to be frequently carried from patient to patient by physicians and nurses." He gives this sentence a very prominent position in the reprint of 1855 as a quotation from the original essay of 1843; and I submit that the careful study of the essay as a whole must compel the reader to the conclusion that this quotation contains the author's whole contribution to obstetric science. The authorities quoted by him throughout, and his practical directions as to the means of preventing the spread of the disease, all go to prove that Holmes was a contagionist like his more thoughtful contemporaries, no more and no less. For example, the remarkable eulogy which he bestows upon Gordon of Aberdeen reveals the essential character of his own opinions. He quotes Gordon's "terrible evidence," and he prints in capital letters Gordon's allegation that he "could venture to foretell what women would be affected." But Gordon treated his cases exactly according to Denman's methods, except that the Aberdeen women revolted at the blistering; and these therapeutic measures prove that he had no new conceptions about the nature of the disease. As to "foretell," Walsh used the identical word with regard to exactly similar circumstances in an essay which he published ten years before Gordon's and which must have been as well known to Gordon as were Denman's works, which he quotes.

The fact is they all held the barren doctrine of contagionism, the spread of the disease by some pervading unknown agency, a miasm, a "cosmic, telluric, atmospheric influence." This doctrine is implied, almost stated, in one of the final paragraphs suggesting methods of preventing the disease from being conveyed by the medical practitioner: "He would do wisely to relinquish his obstetrical practice for at least one month, and endeavour to free himself by every available means from any noxious influence he may carry about with him." No candid interpretation of this paragraph can surely lead to any conclusion except that which I have just stated. It is rank contagionism, not so enlightened as Eisenmann's "Kindbettfeber" published in 1834. But O. W. Holmes himself laid no claim to originality or to any discovery; the distinction was thrust upon him in his later years by admirers of the distinguished man of letters who magnified out of all recognition the services of the undistinguished man of science.

"I do not expect ever to return to this subject," Holmes wrote when commenting on the amenities of controversy to which he and his essay had been subjected by some opponents. Could the discoverer of the cause of a pestilence which was year by year hurrying innumerable young mothers prematurely to the grave, and, to use his own words, bowing the strength of manhood into the dust, could such a man have ever found it possible to abandon "this subject"? Yes, if only the subject of a semi-literary task; no, if the subject of a creed and of a crusade to which a man's whole life must be devoted.

Now after considering this calm, philosophic, though eloquent, exposition of the contagious doctrine and its practical consequences, let us turn to the achievement of Semmelweis and his devotion to that which he conceived to be his duty to humanity. Can any man read without pity and admiration the tragic story of the discovery and its disastrous consequences to the discoverer in his life-long struggle to spread his doctrine and to stay the plague? We deplore while we sympathise with the sufferings of the tender-hearted man, helpless amidst the scenes of misery and death in the Vienna hospital, but we are soon filled with admiration for the steadfast will and the clear intellect which grasped the relevant constant elements amidst the apparent chaos of elusive details and conflicting circumstances, and ultimately brought certain factors into causal relationship with the phenomena of the disease. Semmelweis had solved a problem which had baffled the most observant and philosophic physicians for many generations.

The pestilence no longer depends upon some mysterious "influence"; it is reduced to the pyæmia already too well known to surgeons. It is the squalid product of filth, of actual contact with decomposing animal matter. "The carrier of the decomposed animal organic matter is the examining finger, the operating hand, the instruments anything which can be rendered unclean and then brought into contact with the genitals of the parturient or recently delivered woman." To compare this doctrine with opinions prevalent in New England or elsewhere about the same time is to compare unlike things; between them there is hardly a *tertium quid*. Semmelweis himself well expressed the consequent practical difference: "When English practitioners have the misfortune to lose several lying-in patients they are not satisfied with disinfection by means of washing with chlorine, but they set aside their midwifery practice for some weeks or take a tour of several weeks' duration in order to get completely rid of the puerperal contagion. We destroy the decomposed material by means of chloride washings and hold this disinfection for sufficient."¹

Here was the position which Semmelweis had reached after much tribulation. "I do not expect to return to this subject," exclaimed Holmes. Semmelweis was never to leave "this subject"; he was to devote his sad existence to the pathetic struggle to establish "Meine Lehre." "Should it so happen, which God forbid, that it is not vouchsafed to me to see with my own eyes the happy time when both inside and outside the maternity hospitals of the whole world only cases of self-infection may be occasionally found, still the conviction that such a time must come sooner or later after me will brighten my dying hours (*erheutern*)."

Fritsch, writing a quarter of a century later, declared: "In the history of obstetrics there is a dark page, and its heading is 'Semmelweis.' Who could avoid feeling the powerful impression produced by his book? Even to-day whole pages of his deductions might stand in the most modern work. And the annihilating logic of his statistics! We young men to whom antipathies were unthinkable! We whom coarse tirades against 'genius misunderstood' were only wearisome reading, we find it incomprehensible that the logical conclusions from the doctrine of infection were nowhere drawn."

But although the "*Lehre*" was at first greeted with derision or hostility by the occupant of almost every chair of obstetrics in Europe, the logical conclusions came ultimately to be drawn and applied everywhere. Much had to be done by bacteriologists and by surgeons, especially by our own Lister, before the vast service to mankind which had been rendered by Semmelweis came to be seen in its due proportion; but the era which he foresaw has arrived, and it is now generally, almost universally, recognised that to

Semmelweis, and to him alone, we owe the modern etiology and pathology of childbed fever—"Puerperal-Fieber ist Wund-Fieber: Wund-Fieber ist Wundvergiftung," and "all infection comes from without." Upon these doctrines our prophylaxis and our therapeutics are entirely based.

I am, Sirs, yours faithfully,

Manchester, Jan. 21st, 1907.

WILLIAM J. SINCLAIR.

To the Editors of THE LANCET.

SIRS,—Your annotation on "The Respective Merits of Semmelweis and Oliver Wendell Holmes in the Treatment of Childbed Fever" does not give credit to the man who first proclaimed its highly contagious character—viz., Gordon of Aberdeen; and although according to Dr. T. C. Allbutt of Cambridge "the benefactor to whom the world's gratitude and memorial are due is he who makes the thing go," we must not forget him, who at such an early date did what was possible in his day to enlighten the profession on the subject.

I am, Sirs, yours faithfully,

JOHN HADDON, M.D. Edin.

Denholm, Hawick, Jan. 22nd, 1907.

THE INTRAMEATAL OPERATION.

To the Editors of THE LANCET.

SIRS,—May I be allowed to once again encroach upon your valuable space in order to reply to the inaccuracies contained in Mr. F. Faulder White's letter in THE LANCET of Jan. 5th, to which my attention has only just been drawn.

Mr. White is under a serious misapprehension when he says that he is gratified to find that I am "now in favour" of the intrameatal operation. If he will consult the *Clinical Journal* of May 24th, 1899, he will find a paper by me on Ossiculectomy which will convince him that I have been "in favour" of that procedure for some considerable time. As regards the paper on the mastoid operation to which he refers, I in no way withdraw one single word of what I then wrote. Mr. White (who at one time advocated the curing of every case of otorrhœa by irrigation) has written much about his operation, to which he has given the name of "otectomy" (literally, removal of the ear), but I have never read any account of it that does not plainly show it to be merely an ossiculectomy, with removal of the outer attic wall. The latter addition I, in common with other otologists, have done for several years past, as reference to the Transactions of the Otological Society will show. Mr. White writes as if he alone had advocated ossiculectomy and that in the face of opposition from every otologist; as a matter of fact, Mr. White, starting with universal irrigation, now pushes universal "otectomy" as zealously as he once insisted on the wickedness of operating at all.

In conclusion, I would like to add one word of comment upon Dr. Frederick Spicer's letter in THE LANCET of Jan. 5th. Mr. Charles J. Heath's former paper was read before the Otological Society and was there severely criticised, and most justly so.

I am, Sirs, yours faithfully,

MACLEOD YEARSLEY.

Upper Wimpole-street, W., Jan. 17th, 1907.

ABORTION AMONG THE ANCIENTS.

To the Editors of THE LANCET.

SIRS,—Referring to an annotation under this title published in THE LANCET of Jan. 19th, p. 178, where a recent paper by me is discussed, allow me to state briefly that your critic or reviewer does not seem to have understood me perfectly.

I never dreamed of saying that "abortion was not considered immoral by the early Christians," but I stated that neither the Old nor the New Testament mention that subject. I showed that among the Pagan philosophers opinions varied about the immorality of abortion, but that there is good reason for supposing that the so-called Orphic sects condemned abortion very strongly. The same horror for the practice of abortion was found to prevail in early Christian literature (later than the Gospels), is in accordance with the morals of Orphism, and may very well have borrowed its expressions from that source. All those who have studied the "Purges of Orpheus in the Roman catacombs and the texts of the early Fathers, claiming Orpheus as a disciple of Moses, will readily acknowledge the possibility of an Orphic influence on the written morals of Christianity, wherever the point at issue has been left untouched by the Holy Writ.

I never said or thought that Virgil, in the passage, *Æneid* VI., 426-30, had meant the infant victims of abortion. But it is well known to scholars that Virgil, especially in that part of his poem, imitated and combined Greek sources, often at second hand, and without understanding them as a modern scholar would try to do. Now, I have shown that in the passage in question victims of an unjust, premature, and violent death are grouped together; the only apparent exceptions are the newly born babes. So I ventured to suggest that, in the Greek source lost to us, but known to Virgil and followed by him with some sort of sluggishness, that apparent exception did not exist and that the newly born babes were the victims of abortion. Further, by a quotation of the pseudo-Petrine gospel, which has many points in common with Virgil's Greek and Orphic source, I made it pretty clear that my hypothesis may almost be considered as a certitude, inasmuch as we have a right to reason about a text which we do not possess, with the help of other texts derived from it. I would be astonished if any professional scholar maintained a contrary opinion after having taken cognisance of mine. I am, Sirs, yours faithfully,

Paris, Jan. 22nd, 1907.

SALOMON REINACH.

THE OPERATIVE TREATMENT OF ADHERENT PERICARDIUM AND CARDIAC HYPERTROPHY.

To the Editors of THE LANCET.

SIRS,—On July 28th of last year you did me the favour to publish in THE LANCET a paper on Pericarditis in Childhood. My chief incentive in publishing that paper was the hope—not realised—that my proposals for the surgical treatment of adhesive pericarditis and cardiac hypertrophy might be discussed by physicians and surgeons whether by way of approval or condemnation. I endeavoured to show by a study of the growth of the heart both in embryo and under pathological conditions that what the labouring heart in certain circumstances requires is more room, whether to grow in or to act in. I mentioned that to the derision of a reviewer of my book on "Cardiac Failure" (1897) I had indicated cardiac symphysiotomy as a possible triumph of surgery and was met with the retort that I had in any case exhibited a triumph of imagination. Towards the end of my paper I remarked: "I am aware that in speaking thus (in advocacy of the procedure) I do so on theoretical grounds and not from actual experience, but such thought has frequently preceded action ultimately justified by results, and I am not unhopful that surgery, which has accomplished so much, may also in well-defined circumstances find a place in some cases of adherent pericardium. To return to our embryo, the growing organ requires a surplus of room to grow in; the overgrown organ requires more room to work in, and it may be that tethered by extraneous adhesion, or not so restricted, the hypermyotic heart may in the future and in some cases be provided with such by the genius and courage of some surgeon bold enough to undertake the task."

I was not aware when I wrote this passage, and indeed not until I read an interesting article on Some Points in the Pathology and Treatment of Adherent Pericardium by Professor Wenckebach of Groningen, which appeared in the pages of your contemporary the *British Medical Journal* (Jan. 12th, 1907), that all this had already been successfully done by surgeons acting under the inspiration of Professor Brauer of Heidelberg. The paper of the latter is published in Langenbeck's *Archiv für Klinische Chirurgie* (Vol. LXXI., 1903), and relates the result of the procedure in three cases. His patients were two men and a youth, aged respectively 50, 25, and 16 years. The principle of the operation undertaken was to provide the heart with more room to act in and less obstacle to pull against, and no attempt was made to open the pericardium or to break down possibly existent adhesions either within the sac or beyond the area of the external opening in the thorax which was made by the removal of ribs and cartilages and a portion of the sternum sufficient to allow of freer movement of the heart. In fact, there is nothing positive to show, notwithstanding the criteria of differential diagnosis given, that such adhesions existed, except that in the case of the man, 25 years of age, who died from influenza pneumonia ten months after decidedly beneficial operation, the pericardial sac was proved post mortem to be adherent to the heart. In Professor Wenckebach's case also, although

the diagnosis of adherent pericardium was made and the history warranted the diagnosis, costo-pericardial adhesions were not found and the sac was not opened. Nevertheless the result of allowing the hypertrophied heart more space to act in, and permitting it to gain that space through a non-resistant surface and not at the expense of the bone-bound thoracic contents, was decidedly beneficial. This is not the place to discuss the many interesting scientific questions which Brauer and Wenckebach raise in their papers, but I have mentioned the details given for this reason—namely, that Brauer's operation seems indicated, not merely in the comparatively rare cases of viscero-costo-pericardial adhesion, but also in the much commoner cases of hypermyosis of the heart with valvular lesion and without extraneous tethering.

The importance of a correct diagnosis, it appears to me, after reading Brauer's and Wenckebach's cases, is less as to whether we have actually to deal with adherent pericardium than as to whether we have to do with notable hypertrophy with or without dilatation, or with cases in which notable and persistent dilatation is the chief cause of a state which threatens the life of the patient. This is not always an easy matter to determine. For systolic recession of the interspaces may often be observed with a bulky heart which is untethered and which, from its very enlargement, is comparatively fixed in its extended area.

Thus, I had under my care last year at the Children's Hospital, Paddington Green, the case of a girl, 14 years of age, whose large, distressed heart with paradoxical pulse I regarded as one of adherent pericardium, but who improved so much under ordinary cardiac treatment as to render this supposition doubtful. She was indeed quite convalescent, but unfortunately contracted typhoid fever of a severe type and went through it for a month. At the end of that time she died exhausted but without notable retrograde stasis of the circulation, and at the necropsy her heart was found to be quite without hampering adhesions, and while hypertrophied and dilated not excessively so. It was a case of mitral stenosis. Even, however, should erroneous diagnosis in some cases lead to the operation of cardiomyolysis, as Brauer terms it, it is unlikely that the hypertrophied heart, judging from the results of the cases published, would be other than benefited by this procedure.

I must apologise, Sirs, for occupying so much of your space, but I consider the subject an important one, and it is one which has interested me for some ten years or so. I only blame myself for a conservative timidity which has prevented my putting these conclusions into practice sooner, and hope soon to have an opportunity of acting otherwise, in view of the results secured by Brauer and Wenckebach.

I am, Sirs, yours faithfully,

ALEXANDER MORISON.

Upper Berkeley-street, W., Jan. 28th, 1907.

TYPHUS FEVER IN TENERIFFE.

To the Editors of THE LANCET.

SIRS,—I have read with great interest the letter on this subject by Dr. W. H. Peile which appeared in THE LANCET of Jan. 26th. May I add the following? About a fortnight ago, whilst I was on board, the s.s. *Medio* called at the town of Santa Cruz, Teneriffe. She remained there 24 hours, but during that time no passengers were allowed to go ashore because of the existence of a few cases of typhus fever on the island. So far so good. The sanitary authorities of Santa Cruz, however, permitted dozens of semi-coloured hawkers to board the *Medio*. These hawkers, coloured, dirty, and repulsive, came aboard with fruit, silks, linens, &c. There is little doubt from what localities of Santa Cruz these people must have come—most probably from the fever-infested portions. Is this the usual way in which quarantine regulations are enforced?

I am, Sirs, yours faithfully,

Edinburgh, Jan. 25th, 1907. E. ACHER-BROWN, M.B. Edin.

MEAT DIET AND THE TEETH.

To the Editors of THE LANCET.

SIRS,—In a letter on this subject published in THE LANCET of Jan. 26th Dr. Edmund Spriggs gives a candid criticism on some facts and opinions which I presented at a recent meeting of the Pathological Society, and which were reported in your issue of Dec. 29th, 1906. As some of the statements

in this letter may have given your readers an erroneous impression both as to the facts and to the author's interpretation of them, perhaps you will kindly allow me to reply to his criticism.

Dr. Spriggs states that "in the specimens shown at the Pathological Society on Dec. 18th, 1906, a distinct difference was apparent between a tooth germ in the meat-fed and one in the bread-and-milk-fed animal. The section of the head of a meat-fed rat, thrown upon the screen in order to demonstrate the bone changes, showed a developing tooth which was not a normal one," &c. The first of these statements is correct; the second is entirely wrong. Dr. Spriggs having been led into error through an imperfect acquaintance with the fallacies involved in this department of histological work. As the point may be of some interest to future observers and can be more authoritatively dealt with by an expert, I have asked Mr. Gibbs to reply to Dr. Spriggs's comment on the histological appearances of the teeth.

My critic further writes: "At that meeting of the Pathological Society I suggested, as reported in THE LANCET of Dec. 29th, 1906, that Dr. Chalmers Watson was mistaken in ascribing many of the effects observed by him to a meat diet and that they were probably due to a deficiency of lime and other bases." In my reply to this criticism I pointed out that my communication was restricted in its scope to a demonstration of the structural changes which had followed the use of an excessive meat diet; it did not include the consideration of the causation of any of the changes observed. The experiments referred to by Dr. Spriggs in support of his contention that the deficiency of lime in the diet was the cause of the structural changes were well known to me, as were also other experimental data relevant to this subject. I had also considered the view that the deficiency of lime might be an important factor in the production of some of the changes but had refrained from forming any definite conclusion on this point, and, with all due deference to Dr. Spriggs's views, I am still of opinion that it is inadvisable to form any theory as to the causation of the structural changes until the investigation is more complete. I would like, however, to point out that the changes in the osseous system, which seem to have particularly attracted Dr. Spriggs's attention, are, in my opinion, among the least important of the structural changes demonstrated at my meeting.

The most important point in Dr. Spriggs's letter remains to be dealt with—viz., the statement: "Indeed, whether the results produced in rats are due to the want of lime and other bases or whether they are an expression of the failure of a naturally omnivorous animal to rapidly adapt itself to a purely flesh diet it is clear that they cannot be directly applied to the case of civilised man, who never in ordinary circumstances lives upon a diet of meat alone." This criticism raises an issue of very great interest and importance and with your permission I would like to answer it in some detail. Before doing so, however, I would like to feel assured that I correctly interpret Dr. Spriggs's position in regard to some facts relevant to the issue which were demonstrated at the meeting of the Pathological Society. Might I ask him whether there is, in his opinion, any essential difference between the histological appearances of the bones in the second generation of meat-fed rats and those of the bones of the infant aged 16 months, the child of a tuberculous subject who had been fed for a prolonged period prior to and during gestation on a diet containing a great excess of meat? Photographic reproductions of the actual slides shown at the meeting are given in a paper published in THE LANCET of Dec. 8th, 1906.

I am, Sirs, yours faithfully,

CHALMERS WATSON.

Edinburgh, Jan. 27th, 1907.

To the Editors of THE LANCET.

SIRS,—In reply to the first part of Dr. E. I. Spriggs's letter in THE LANCET of Jan. 26th, p. 252, I must express my surprise that he should come to any conclusions as to the histology of a tissue merely from seeing thrown on a screen a photomicrogram of a low-power magnification of an object which he had never examined under the microscope itself. Dr. Spriggs is also possibly unaware of the very great difficulties that beset the histological investigation at the same time of such fully calcified tissues as enamel and dentine and of the soft tissues immediately in contact with them. Owing to very great numbers of sections having to be cut and examined the paraffin method was the only practicable

one, the result being that a certain proportion of sections, so far as the dental tissues were concerned, had to be discarded owing to the very obvious artifacts they showed. I have re-examined *microscopically* the sections, photographs of which Dr. Spriggs saw on the screen, and it may interest him to know that for the purposes of the investigation both of these sections were rejected for this reason. I might also point out that in investigating such a difficult subject one does not draw conclusions from a comparison of any two sections but from a comparison of a very large number.

b) The photo-micrograms shown by Dr. D. Chalmers Watson were not from any of the three rats I referred to as having hypoplastic teeth; and, as stated in a previous letter, neither Mr. G. W. Watson nor I was able to detect any sufficiently constant variations in the tissues, hard or soft, to warrant us in concluding that there were any essential histological differences between the teeth of meat-fed and of bread-and-milk-fed rats. I am, Sirs, yours faithfully,

Edinburgh, Jan. 27th, 1907.

J. H. GIBBS.

THE PROPHYLAXIS OF CANCER AS INDICATED BY THE PARASITIC THEORY.

To the Editors of THE LANCET.

SIRS,—No one can have followed the progress of cancer research in this and other countries without being impressed with the vast extent of the knowledge which has been acquired in recent years, and yet he must also be impressed by the present limitations of that knowledge and must feel how little progress has been made in the matter of actual dealing with the disease. In the course of this research certain facts relating to cancer seem to have come into special prominence of late. To the writer, as an outside observer, these seem to be the following: (1) the widespread and almost universal distribution of cancer; (2) the extraordinary powers of growth exhibited by the cancer cells within the body; (3) the great vitality exhibited by these cells without the body; and (4) the ever-increasing evidence that in a large proportion of cases of cancer infection is by direct inoculation from without.

These facts seem to throw some light on those portions of the life-history of cancer which hitherto have lain in obscurity. Of one part of that life-history we know something. We trace the primary growth presumably from a single cell. This by its rapid growth soon becomes a tumour containing thousands of cells, each of which when carried away by the lymph or blood may become a secondary growth. Thus by the end of life one cell has become a million, and then with the patient's death they once more pass out of our sight. These facts to which I have referred seem, however, to indicate that the life-history of cancer does not end with the life-history of its host, but that long persisting in the bodies of the dead they may in all probability withstand the forces which destroy those tissues and in some resistant spore-like form become by slow degrees disseminated through the soil, carried by worms or birds, or by the deep water channels and thus account for the far-reaching distribution of the disease, its universality, and its widespread incidence. If this be so, it bears some analogy to the dissemination of tubercle bacilli, with their wide distribution in nature, their great resistant powers during extra-corporeal life, and their somewhat difficult "adhesion" to the human host, and their powers of growth when once they gain access to that host.

In the present argument the cancer cell is regarded as the infecting agent. This is generally admitted to be the case when dissemination takes place within the body and the effect of radical operation strongly supports this view. Evidence has been brought forward to show the extraordinary powers of resistance to chemical agents, cold, &c., of these cancer cells outside the body and the history of cancer-infected mice cages and of cancer houses is also in favour of their vitality being long maintained under such conditions. The primary incidence of cancer, so rarely on the lungs, but so commonly on external surfaces and again, at similar points where the blood stream might carry heavy organisms, such as a cell, which is very widely distributed in nature, and which may, though with difficulty, be inoculated from food, clothing, or other means of contact, but which is hardly ever air-borne. The difficulty of

inoculation bears resemblance to that of tubercle, only is much more marked. Once established, however, the powers of growth in the human body are far greater, but the tissue reaction excited is much less, this, again, being in favour of an infection due to some cellular organism closely resembling the body cells rather than to any extraneous micro-organism.

Finally, the contrast between the growth and multiplication of these cells within and without the body is most remarkable. Within we can trace the development from a single cell of the millions of cells represented by the secondary growths of "general dissemination." Without, while we have much evidence of the maintained vitality of the cancer cells, we know of no conditions under which they may continue to grow or to multiply. In the human subject we recognise that the virulence and infectivity of cancer vary in direct ratio to the rapidity of cell growth—in other words, to the number of cells. Is it not, therefore, reasonable to suggest that the widespread distribution of cancer is due to those myriads of cells committed to the soil with every patient dying from cancer, which subsequently by slow degrees become disseminated throughout nature?

Turning now to the question of the treatment of cancer, we feel that so far little progress has been made. No specific has yet been found and no antiserum has been obtained. Vaccine treatment in the case of mice seems to have given some result, but the difficulties of applying any such treatment to the human subject can readily be imagined and we still remain with only one cure—namely, early and complete excision. In recent years medical science has been increasingly occupied with the prevention rather than with the cure of disease. In the case of tubercle the importance of this is being more and more realised, as we see in the active crusade against the dissemination of tuberculous sputa and the efforts at isolation of advanced cases. No effort, however, seems to have been made to deal with that large source of tubercle bacilli which is found in the dead bodies of tuberculous patients which probably contributes largely to the distribution of the bacilli in nature. This may be of importance in tubercle, but from the arguments above brought forward is far more likely to be so in the case of cancer. Hence the writer would put forward a strong plea for an attempt at the prophylaxis of cancer, a goal which should not be unattainable if the above suppositions are correct. Granted this, the prophylaxis should be relatively easy, for in this case the great source of infection must be the bodies full of secondary growth which are committed to the soil at death, while other sources, such as cancerous discharges and infected excreta, are comparatively unimportant and easily dealt with.

The cancer cells are readily destroyed by heat, and thus if cremation of all those dying from cancer can be legally enforced the great source of the disease will be eliminated, and it is not unreasonable to hope that by such methods a gradual diminution in the frequency of the disease or even its ultimate eradication may be attained. The writer can lay no claim to any share in the work of cancer research which has been carried on with so much ability and perseverance, but having followed its progress with the deepest interest he ventures to bring forward those suggestions which have been prompted by the work of others.

I am, Sirs, yours faithfully,

H. V. WENHAM.

St. Bartholomew's Hospital, E.C., Jan. 23rd, 1907.

ELECTRIC LIGHT IN MARYLEBONE.

To the Editors of THE LANCET.

SIRS,—Your reference to the failure of the electric light in Marylebone within the past few weeks and your warning to surgeons undertaking to perform operations with the aid of artificial light within the limits of the borough to provide against the recurrence of such a contingency is extremely opportune. However, the statement that while such events are unusual in other parts of London they have been frequent in Marylebone since the council undertook the lighting is more open to question. As a user of electric light, both under the old régime and since it has been taken over by the borough, I am in a position to say which is the greater weekly occurrence. Indeed, the failures were so frequent that a deputation of medical practitioners waited upon the council and asked them to take some action to put an end to

the diagnosis of adherent pericardium was made and the history warranted the diagnosis, costo-pericardial adhesions were not found and the sac was not opened. Nevertheless the result of allowing the hypertrophied heart more space to act in, and permitting it to gain that space through a non-resistant surface and not at the expense of the bone-bound thoracic contents, was decidedly beneficial. This is not the place to discuss the many interesting scientific questions which Brauer and Wenckebach raise in their papers, but I have mentioned the details given for this reason—namely, that Brauer's operation seems indicated, not merely in the comparatively rare cases of viscero-costo-pericardial adhesion, but also in the much commoner cases of hypermyosis of the heart with valvular lesion and without extraneous tethering.

The importance of a correct diagnosis, it appears to me, after reading Brauer's and Wenckebach's cases, is less as to whether we have actually to deal with adherent pericardium than as to whether we have to do with notable hypertrophy with or without dilatation, or with cases in which notable and persistent dilatation is the chief cause of a state which threatens the life of the patient. This is not always an easy matter to determine. For systolic recession of the interspaces may often be observed with a bulky heart which is untethered and which, from its very enlargement, is comparatively fixed in its extended area.

Thus, I had under my care last year at the Children's Hospital, Paddington Green, the case of a girl, 14 years of age, whose large, distressed heart with paradoxical pulse I regarded as one of adherent pericardium, but who improved so much under ordinary cardiac treatment as to render this supposition doubtful. She was indeed quite convalescent, but unfortunately contracted typhoid fever of a severe type and went through it for a month. At the end of that time she died exhausted but without notable retrograde stasis of the circulation, and at the necropsy her heart was found to be quite without hampering adhesions, and while hypertrophied and dilated not excessively so. It was a case of mitral stenosis. Even, however, should erroneous diagnosis in some cases lead to the operation of cardiolysis, as Brauer terms it, it is unlikely that the hypertrophied heart, judging from the results of the cases published, would be other than benefited by this procedure.

I must apologise, Sirs, for occupying so much of your space, but I consider the subject an important one, and it is one which has interested me for some ten years or so. I only blame myself for a conservative timidity which has prevented my putting these conclusions into practice sooner, and hope soon to have an opportunity of acting otherwise, in view of the results secured by Brauer and Wenckebach.

I am, Sirs, yours faithfully,

ALEXANDER MORISON.

Upper Berkeley-street, W., Jan. 26th, 1907.

TYPHUS FEVER IN TENERIFFE.

To the Editors of THE LANCET.

SIRS,—I have read with great interest the letter on this subject by Dr. W. H. Pells which appeared in THE LANCET of Jan. 26th. May I add the following? About a fortnight ago, whilst I was on board, the s.s. *Medio* called at the town of Santa Cruz, Teneriffe. She remained there 24 hours, but during that time no passengers were allowed to go ashore because of the existence of a few cases of typhus fever on the island. So far so good. The sanitary authorities of Santa Cruz, however, permitted dozens of semi-coloured, hawkers to board the *Medio*. These hawkers, coloured, dirty, and repulsive, came aboard with fruit, silks, linens, &c. There is little doubt from what localities of Santa Cruz these people must have come—most probably from the fever-infested portions. Is this the usual way in which quarantine regulations are enforced?

I am, Sirs, yours faithfully,

Edinburgh, Jan. 26th, 1907. E. ARCHER-BROWN, M.B. Edin.

MEAT DIET AND THE TEETH.

To the Editors of THE LANCET.

SIRS,—In a letter on this subject published in THE LANCET of Jan. 26th Dr. Edmund Spriggs gives a candid criticism on some facts and opinions which I presented at a recent meeting of the Pathological Society, and which were reported in your issue of Dec. 29th, 1906. As some of the statements

in this letter may have given your readers an erroneous impression both as to the facts and to the author's interpretation of them, perhaps you will kindly allow me to reply to his criticism.

Dr. Spriggs states that "in the specimens shown at the Pathological Society on Dec. 18th, 1906, a distinct difference was apparent between a tooth germ in the meat-fed and one in the bread-and-milk-fed animal. The section of the head of a meat-fed rat, thrown upon the screen in order to demonstrate the bone changes, showed a developing tooth which was not a normal one," &c. The first of these statements is correct; the second is entirely wrong. Dr. Spriggs having been led into error through an imperfect acquaintance with the fallacies involved in this department of histological work. As the point may be of some interest to future observers and can be more authoritatively dealt with by an expert, I have asked Mr. Gibbs to reply to Dr. Spriggs's comment on the histological appearances of the teeth.

My critic further writes: "At that meeting of the Pathological Society I suggested, as reported in THE LANCET of Dec. 29th, 1906, that Dr. Chalmers Watson was mistaken in ascribing many of the effects observed by him to a meat diet and that they were probably due to a deficiency of lime and other bases." In my reply to this criticism I pointed out that my communication was restricted in its scope to a demonstration of the structural changes which had followed the use of an excessive meat diet; it did not include the consideration of the causation of any of the changes observed. The experiments referred to by Dr. Spriggs in support of his contention that the deficiency of lime in the diet was the cause of the structural changes were well known to me, as were also other experimental data relevant to this subject. I had also considered the view that the deficiency of lime might be an important factor in the production of some of the changes but had refrained from forming any definite conclusion on this point, and, with all due deference to Dr. Spriggs's views, I am still of opinion that it is inadvisable to form any theory as to the causation of the structural changes until the investigation is more complete. I would like, however, to point out that the changes in the osseous system, which seem to have particularly attracted Dr. Spriggs's attention, are, in my opinion, among the least important of the structural changes demonstrated at my meeting.

The most important point in Dr. Spriggs's letter remains to be dealt with—viz., the statement: "Indeed, whether the results produced in rats are due to the want of lime and other bases or whether they are an expression of the failure of a naturally omnivorous animal to rapidly adapt itself to a purely flesh diet it is clear that they cannot be directly applied to the case of civilised man, who never in ordinary circumstances lives upon a diet of meat alone." This criticism raises an issue of very great interest and importance and with your permission I would like to answer it in some detail. Before doing so, however, I would like to feel assured that I correctly interpret Dr. Spriggs's position in regard to some facts relevant to the issue which were demonstrated at the meeting of the Pathological Society. Might I ask him whether there is, in his opinion, any essential difference between the histological appearances of the bones in the second generation of meat-fed rats and those of the bones of the infant aged 16 months, the child of a tuberculous subject who had been fed for a prolonged period prior to and during gestation on a diet containing a great excess of meat? Photographic reproductions of the actual slides shown at the meeting are given in a paper published in THE LANCET of Dec. 8th, 1906.

I am, Sirs, yours faithfully,

CHALMERS WATSON.

Edinburgh, Jan. 27th, 1907.

To the Editors of THE LANCET.

SIRS,—In reply to the first part of Dr. E. I. Spriggs's letter in THE LANCET of Jan. 26th, p. 252, I must express my surprise that he should come to any conclusions as to the histology of a tissue merely from seeing thrown on a screen a photograph of a low-power magnification of an object which he had never examined under the microscope itself. Dr. Spriggs is also possibly unaware of the very great difficulties that beset the histological investigation at the same time of such fully calcified tissues as enamel and dentine and of the soft tissues immediately in contact with them. Owing to very great numbers of sections having to be cut and examined the paraffin method was the only practicable

allow his valet to pour out more, and ordered him to take it to me to see if I could explain the cause. A few simple tests soon told it was contaminated with copper. I observed the flask, which was made of copper, had been once "tinned" inside and silver-plated outside. The tin coating had all been eaten away and the copper walls could be easily seen. I advised the gentleman to procure a glass flask in future and he would be saved a like experience.

I am, Sirs, yours faithfully,

Exeter, Jan. 23rd, 1937

A. R. CLARK.

ADVERTISEMENT BY POST.

To the Editors of THE LANCET.

SIRS.—As an appendix to the history of the year which has just closed it may interest your readers to have placed upon record the number of advertisements the writer has received through the post during the last four years.

His name first appeared in the Medical Register and in Churchill's "Medical Directory" in 1933. The address given was just beyond the four-mile radius in the North-Eastern postal district of the metropolis—that is, it appeared to be that of an ordinary general practitioner and not of "a consultant." From the first it was decided to note down in a diary the actual number and the cost of the postage of the advertisements by post which were received during the year, for an early assurance was given (by post) that "a letter or post-card is the cheapest and most reliable traveller" and that "a halfpenny stamp is the best advertiser." The personal calls of agents, travellers, canvassers, and touts were not recorded. On very few occasions were proffered samples applied for. In each year August was the month when the fewest communications were received—namely, on an average, a dozen. The largest number was received at varying periods, thus: in 1933, December, with 30; in 1934, October, with 44; in 1935, May, with 46; and in 1936, March, with 52.

A rough classification of the nature of the advertisements was made; a few examples are appended. As was to be expected the very large majority referred to proprietary preparations, drugs, special food-stuffs, papers, medical publishers' circulars, catalogues, and price lists. Several of these were repeated monthly—this recurrent insistence and persistence was not confined to American advertisers. Very few peculiarly local advertisements were received and practically no begging letters. The fair fame of the record was tarnished for the first time during the very last week when a lottery prospectus was received despatched from Copenhagen. This year four technical diaries came to hand.

The following is a statistical summary:—

	1933	1934	1935	1936
Total advertisements received through the post	245	310	371	330
Spirits, wines, and tobaccos	19	10	20	37
Insurance societies' prospectuses	17	13	23	11
Samples (uninvited)	16	22	13	9
Nursing homes and retreats	12	14	15	14
Moneylenders	4	12	10	7

The figures for 1933 are abnormal as the register of names published in 1932 probably was used by advertisers in the early part of the following year. In addition to the figures given above for 1936 the following may be quoted: drugs, foods, &c., 150; papers and price lists, 74; mineral waters, spas, &c., 13 (chiefly in April); instruments, appliances, and other goods, 44.

The cost of postage was recorded during the last three years. The cost of the carriage of samples is not included and a few stamps from Italy, Switzerland, and Denmark are omitted.—In 1934: £1 2s. 0d.; 48 cents; 55 centimes; 30 pfennigs. 1935: £1 0s. 10d.; 40 cents; 95 centimes; 30 pfennigs. 1936: £1 0s. 6d.; 40 cents; 80 centimes; 50 pfennigs. This means that the revenue from such postage was about 25s. in the case of each medical practitioner to whom these advertisements were sent—a not inconsiderable sum when it is remembered that about 20,000 medical practitioners are registered as living in the British Isles. In the writer's experience, to have one's name in the

Law List induces very few advertisers to use the post office service for a similar purpose to that detailed above.

I am, Sirs, yours faithfully,

STANLEY B. ATKINSON.

Cawley road, N.E., Jan. 31st, 1936.

MANCHESTER.

(FROM OUR OWN CORRESPONDENT.)

Slaughter of the Innocents.

THE frequent references to the mortality in young children from burning will perhaps be thought wearisome, but the cruelty of the death is so grievous and the loss to the nation is in the aggregate so great, that the question may well be asked again. Can nothing be done to check it? The city coroner, Dr. E. A. Gibson, made some strong remarks on it yesterday, when three cases of fatal burning had to be inquired into. Last week there were four, and there have been 14 since the beginning of the month. In addition "there are eight cases in the Manchester Infirmary practically at the point of death suffering from burns." Yesterday also an inquest was held on a child aged four years who was burnt to death at Warrington. The coroner, Mr. Brighouse, said that he had held 20 similar inquests since Nov. 6th. He remarked: "Material wealth was very well, but the wealth of the nation consisted in keeping its children alive." Oldham has added several cases of fatal burning to the total during the past few weeks and yesterday three more were notified to the borough coroner. Another case is reported from near Wigan, where a child aged 11 months was placed in a cradle before the bedroom fire and too near it. And yesterday also the Bury coroner received the report of the death of a girl aged ten years in the Bury Infirmary. On the previous Saturday morning she and a young brother were in the house alone. He fell off a stool in front of the fire, and in picking him up her flannelette skirts caught fire and she was fatally burnt. But danger is not confined to fire alone, for the same catalogue of slaughter includes the case of the young daughter of a labourer at Bradwell who was playing near the fire, her mother being absent, when a pan of boiling water fell on her and she was terribly scalded. This is a serious and shameful record, not standing alone, but one that might be repeated many times over from the country at large, yet, as Mr. Brighouse said, "so far the legislature was unmoved by the appeals of coroners and the Prevention of Cruelty Society." Dr. Gibson fears that the public do not realise the gravity of the question or something more would be done. There seems to be an agreement among coroners that the absence of fireguards is a frequent cause of these so-called accidents and they would have their use made compulsory. As Dr. Gibson says, "parents might be punished for not taking proper precautions to protect their children from fire, and people might be prevented from clothing their children in inflammable garments, particularly flannelette," which is especially dangerous in its ordinary state, though there are some varieties of it where the danger is greatly lessened. But the mothers look at the price of the material and prefer the cheap and dangerous to the safer if the latter is a fraction higher in price. As the laudable effort made by the Mayor of Huddersfield, followed, as it has been and seems likely to be, in other places, has been successful in largely reducing the infantile death-rate, something of the kind might be tried in order to save the children from death by burning. The plan does not appeal to the higher motives, but though it rests on the love of money rather than on the love of their offspring, the result is that the mothers take more care of their children than they did. It pays to keep them alive and a similar plan might serve the children as an insurance against fire.

Overlying.

Three cases of children being found dead in bed were inquired into by the city coroner a few days ago. In one case the mother said that the child was "apparently all right" when she went to bed early on Sunday morning, but later she had found it dead on her arm. She had had 15 children, of whom five died while babies. Inquests were held on two of them who were about a month old. The jury returned an open verdict on account of these inquests having been held, but the coroner said that it would facilitate matters

or mitigate what was described as a nuisance and a positive danger. One eminent surgeon went on to describe how a day or so previously, while he was performing a serious operation on a child, the light had suddenly gone out and how he had grasped the severed end of an artery between finger and thumb while with the other hand he groped for his waistcoat-pocket for a wax vesta to give some light while candles were being procured.

It was this that largely influenced me as a member of the borough council in supporting the proposal that the municipal authorities should take over the electric lighting of the borough. I am not defending them; they may have acted unwisely in the matter, but it is as well to remember that great pressure was brought to bear on them at the time by a large and important section of the consumers, including the surgeons in the district.

I am, Sirs, yours faithfully,

Thayer-street, Manchester-square, W.

M. C. WALSH.

AMYL NITRITE IN HÆMOPTYSIS.

To the Editors of THE LANCET.

SIRS,—Permit me to make a final reply to the last communication of Dr. Francis Hare in THE LANCET of Jan. 19th. I have not been guided by preconceived theories but by clinical facts respecting the hæmostatic action of amyl nitrite and references in the literature to such facts were cited in my last letter. Dr. Hare expresses correctly my theory of action of the drug in question. The fact that the drug is equally efficacious whether given intravenously, by the mouth, or by inhalation is no evidence in contravention of my theory. Chloroform whether administered by inhalation or through other portals is capable of exercising its narcotic properties, and like amyl nitrite may excite profound reflex phenomena by virtue of its local irritant action on the nasal mucosa. Such phenomena range from coughing to cardiac inhibition. Because the hæmorrhage following the removal of parovarian cysts and that of ectopic gestation is controlled by amyl nitrite is no evidence in refutation of my theory until it has been demonstrated that in the structures implicated there are no muscular fibres. Finally, respecting the vaso-motor hypothesis advocated by Dr. Hare in explanation of the mechanism of the asthmatic paroxysm, if the hypothesis in question were correct, then amyl nitrite would in its action fulfil the requirements of the old principle—viz., "*Naturam morborum ostendunt curatione.*" The fact is that amyl nitrite is rarely efficacious, even temporarily so, in inhibiting a paroxysm, and I believe that anyone who has used it for this purpose will substantiate my statement. The failure of action is evident. In asthma, as I have shown elsewhere, the longitudinal fibres of the bronchial musculature are enfeebled; hence the action of amyl nitrite is correspondingly diminished. In hæmoptysis the action of the drug is more forcibly expressed, inasmuch as we assume that the muscular tonicity of the bronchial musculature is not compromised.

I am, Sirs, yours faithfully,

Paris, Jan. 22nd, 1907.

DR. ALBERT ABRAMS.

THE TREATMENT OF CICATRICES.

To the Editors of THE LANCET.

SIRS,—I fear we do not give the attention to this subject that it deserves, both from the annoyance and disability occasioned by scars, especially adherent ones, and the great relief that may be afforded by suitable treatment. I thought these facts were pretty well understood, but two recent cases, both treated at large hospitals here, suggest that one may venture to draw attention to the subject again. In the first case a dock labourer had suffered an extensive laceration of the outer side of the leg and healing had left a scar two or three inches across. The scar was very thin, of a glazed surface, a bright red in colour, and so adherent to the underlying fascia that the patient was unable to follow his occupation owing to pain and lameness on movement. I introduced a tenotome beneath the skin and separated the cicatrix from the fascia beneath it completely, leaving no wound but the puncture of the tenotome. The man was kept up and by walking about and gentle movements of the skin further adhesions were prevented. He was soon able to resume work and the bright glazed skin became almost normal in appearance, though I confess that owing to the size of the cicatrix I feared sloughing would occur.

In another case a man had had the superficial flexor tendons of the forearm divided and the cicatrix in the skin covering the wound became adherent to the tendons and fascia over an extent of some three inches. He was unable to bend his fingers in the slightest degree on his discharge from hospital. He then presented himself at another of our largest hospitals and was subjected to prolonged treatment, so he says, by elaborate mechanical appliances. Being still unable to flex his fingers and his hand being entirely useless he came to the Bootle Borough Hospital and begged that the hand might be amputated, so that he might replace it with a more useful hook. I declined to oblige him but separated the scar subcutaneously from the tendons beneath it. This, with a subsequent freeing of fresh adhesions by my house surgeon, has enabled him to flex his fingers to such an extent that he is able to get a slight grasp with them, powerful as far as it goes, and to do his work.

I have drawn attention to these cases because they had both been under hospital treatment and had both been discharged suffering from serious disability that was readily overcome. It appears as though we were neglecting some old teaching on the treatment of cicatrices. We should do well to remember how much can be done for these cases and where unsightliness is the only difficulty how astonishingly the damaged skin may regain a normal appearance when separated from adhesions that strangle, rather than develop, its blood-supply.—I am, Sirs, yours faithfully,

Liverpool, Jan. 21st, 1907.

GEORGE A. HAWKINS-AMBLER.

SPIROGRAPHS OR NASAL "BREATH PICTURES."

To the Editors of THE LANCET.

SIRS,—Under the above heading Dr. Wyatt Wingrave in his letter in THE LANCET of Jan. 26th, p. 253, described a spiograph made of vulcanite designed to test the degree of actual or relative nasal patency. Aqueous vapour exhaled through the nostrils is condensed on the cool surface of the vulcanite and a fleeting "breath picture" thus obtained, which may be temporarily fixed by lightly powdering the surface with calcined magnesite or fine starch.

It may be of interest to describe the pneumodograph, designed by Courtade of Paris, by means of which he obtains permanent records of the degree of respiratory nasal sufficiency. The instrument consists essentially of two sufficiency. The instrument consists essentially of two plates of glass, graduated in squares, fixed at right angles to each other, T, by means of detachable catches. One plate of the pneumodograph is held horizontally against the upper lip a short distance below the nostrils, consequently the other plate hangs vertically downwards a few inches in front of the mouth. The patient is asked to breathe several times in the manner habitual to him. Condensation of aqueous vapour on the horizontal plate records the degree of nasal patency and a similar condensation on the vertical plate indicates the presence and degree of buccal respiration. Taken in connexion with one another the two spiographs may be used as a practical test of nasal respiratory sufficiency in any particular case, which is often a more useful factor than the degree of nasal patency alone. Permanent records are readily made by pressing sheets of paper specially impregnated with safranin on the surface of the glass plates, the pink colouring matter being liberated by the condensed aqueous vapour. Courtade's pneumodograph is made by Collin of Paris and can be obtained in London through Messrs. Mayer and Meltzer.

I am, Sirs, yours faithfully,

Birkdale, Jan. 23th, 1907.

ALFRED ERNEST BURROUGHS.

THE ACTION OF POTABLE SPIRITS ON METAL.

To the Editors of THE LANCET.

SIRS,—In THE LANCET of Dec. 29th last, p. 1821, I observe you have a note on brandy being contaminated with copper. Might I be permitted to mention that I had a flask with whisky sent me by a sportsman some years ago? The flask had been filled and was daily carried to the moor, but no occasion had arisen for using the contents for over two weeks, and when the valet was in the act of filling a glass the colour was observed to have changed and had become turbid and dark. The gentleman would not

about three times as many men as women in the institutions, but it is satisfactory to note that the number of children coming under the care of the guardians is diminishing. The pressure on the accommodation is so great that as a temporary expedient the guardians have taken on lease a large factory in the neighbourhood of the workhouse in which they intend to provide accommodation for some 250 paupers. The absolute necessity for this is shown by the fact that there are at present 818 inmates in the workhouse alone, which is 311 above the number which it is officially certified to accommodate.

Jan. 25th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Ayr District Asylum.

Dr. O. O. Easterbrook, the medical superintendent of this asylum, makes in his annual report some comments on insanity which are of more than local interest. He discusses very fairly the question as to the increase of insanity in Scotland. He deducts from the number of total admissions patients who had been in the asylum previously; also patients who had been transferred from other institutions or from their own homes who had formerly been certified. In this way a total admission of 137 is reduced to 110. Of the 110 admissions 27 had suffered from one or more previous attacks for which they had been certified but from which they had recovered. The remaining 83 persons represented those who had been certified as insane and placed under control for the first time. This bears out the statement of the central lunacy authorities that the number of persons placed on the register of the insane for the first time in their lives is year by year not increasing to a greater extent than can be accounted for by the increase of population. Under the causes and kinds of insanity stress is laid on the observation that in no instance could there be excluded, prior to the actual attack of insanity, the existence of a morbidly reacting brain in the patient, the outcome of faulty inheritance, or of faulty modes of living, or of previous disease experiences, or of these combined. Specially important was the evidence afforded by the temperaments of the patients; thus it was often found that persons who had become insane had been known as "queer," or "funny," or "peculiar," and Dr. Easterbrook accentuates the necessity of recognising these and other manifestations as indications of a temperament which supplies a soil favourable to the cultivation of insanity. He holds that persons with such abnormal reactivity might be wholly or largely prevented by intelligent observation and careful upbringing from becoming insane. Such persons being potential subjects for psychoses or neuroses must so far as is within their power avoid all causes which will tend to throw an undue stress on their nervous system, and must live more quietly and more carefully than their fellows if they would avoid a breakdown. He also does not share the view that insanity is to be looked on as a toxæmia; he evidently looks more at the constitutional factor as providing the favourable conditions for the action of the toxin. It is further to be noted that all new cases are admitted to, and kept under treatment in, the hospital department where rest and fresh air as well as medicinal treatment are much relied on for their curative influence.

Infirmaries and the Working Man.

In the *Glasgow Herald* of Jan. 28th a very interesting article contributed by a special correspondent appears on the duty of the working man towards the upkeep of the infirmaries in Glasgow. With reference to the £300,000 still required for the rebuilding of the Royal Infirmary, it is suggested that the managers need not look to the present body of annual subscribers or to the middle class as a whole, but that this burden should be undertaken by the working classes. The first argument brought forward is that the middle classes have already contributed to the Glasgow infirmaries far more than their share for building, endowment, and current expenses. Again, the working classes are liable to forget that the general hospitals exist almost exclusively for them, their families, and dependents. The writer goes on to prove that the working man is able to do much more in this direction than he has hitherto done. Quoting from the last report of

the Chief Registrar of Friendly Societies, it appears that the accumulated funds on Dec. 31st, 1905, of the working classes in their several building societies, friendly societies, co-operative societies, trade unions, and other similar thrift societies, and the Post-Office Savings Banks were £402,256,600, a capital fund reported to be increasing at the rate of £14,000,000 per annum. If it be allowed that one-half of the amount in the Post Office Savings Banks, or £82,800,000, belongs to the middle class, the invested funds amount to £319,456,600, of which Scotland's share (based on population) would be £31,000,000, yielding an income of not less than £1,000,000. Thus no great drain upon the invested capital would be made should the £300,000 still needed for the Royal Infirmary be taken from it and the amount could easily be spread over four years. Finally, it is pointed out that the purely sectional legislation of the last session of Parliament, as indicated in the Trades Disputes Act, the extension of the Workmen's Compensation Act, and the Free Meals for School Children Act, all of which were promoted directly by the Labour Party and cast heavy burdens on the middle-class community, is being answered by a feeling that upon emergency the working classes must be left to find more for themselves.

Jan. 29th.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

The Royal College of Surgeons in Ireland.

THE annual dinner of the Royal College of Surgeons in Ireland took place on Jan. 26th, when the Lord Lieutenant was present and delivered an interesting speech in which, however, he did not commit himself to any party political opinions. He expressed his admiration of the outgoing Chief Secretary, Mr. Bryce. The Attorney-General also spoke of the high qualities of Mr. Bryce and his regret that he was obliged to leave Ireland after such a short term of service. General Lord Grenfell said that he should like to say a word about the Army Medical Department and to express his gratitude to those physicians and surgeons who had given such assistance to it by their advice and example. Before the dinner the honorary Fellowship of the College was formally conferred on Mr. J. Priestley Smith, professor of ophthalmology in the University of Birmingham. It will be remembered that the present President of the College, Mr. H. R. Swanzy, is himself a distinguished ophthalmologist and author.

Cerebro-spinal Meningitis in Belfast.

Four children in one family having succumbed to a toxæmia in the course of 24 hours, an inquest was opened at which Professor W. St. Clair Symmers made a provisional diagnosis of cerebro-spinal meningitis. Other cases have since been reported and considerable apprehension is felt in the city. To-day (Wednesday) 29 cases are reported with fatal issue in 17 of them. There is fear in Dublin lest the epidemic should visit the capital and increase its present very high death-rate. No cases have been reported there, however, and there have been none in Dublin since 1900.

The Consumption Problem in Belfast.

At the last meeting of the public health committee the chairman gave an outline of a projected preventive scheme, when the Lord Mayor (the Earl of Shaftesbury) urged that it was a most important question and hoped it would come before the council at an early date on the recommendation of the committee. A special meeting of the public health committee is to be held with a view of preparing a recommendation to the corporation on the question.

The Irish University Question.

On Jan. 25th Mr. Bryce, M.P., who was then still Chief Secretary for Ireland, delivered a most important speech in which he outlined the scheme which the Government proposes to bring forward for dealing with the problem of university education in Ireland. Practically Mr. Bryce accepts the recommendation of the Lord Chief Baron and four other Commissioners, as contained in Note 2 to the report of the Trinity College Commission. He proposes to make Dublin University the natural parent university for the whole country, and that Trinity College, Dublin, Queen's College, Belfast, Queen's College, Cork, and a new college in Dublin shall be the constituent colleges of the University. The new national university and the new

if they would say whether death was due to suffocation or to convulsions, so the jury later returned a verdict of death from convulsions due to natural causes. How the verdict was arrived at is not mentioned, but perhaps they as well as the coroner thought matters should be facilitated. It is not improbable that if the mothers were sufficiently bribed there would be fewer cases of "overlying."

Plomaine Poisoning at Wigan.

There have been considerable excitement and anxiety lately at Wigan on account of a sudden outbreak of sickness. It appears that 30 or 40 people were taken ill on one day and many more since, so that about 100 people have suffered. Meat bought at one particular shop is suspected. Analyses and bacteriological investigations are being carried out, but no authoritative statement has been made as to the cause of the outbreak, though it is generally attributed to plomaine poisoning.

Bad Meat: Butchers sent to Prison.

A serious case of having in possession diseased meat for sale came before Mr. Yates, K.C., the stipendiary magistrate, at the county police court on Jan. 21st. Three butchers, two of Gorton and one of Ardwick, were summoned for being "in possession of meat deposited for sale and unfit for food." Dr. A. W. Martin, medical officer of health of Gorton, stated that he inspected the meat with Mr. Ingram, veterinary surgeon, and the right hind- and fore-quarters of a beast were condemned and removed. When Longden, one of the Gorton butchers, was asked by Mr. Holburn, chief veterinary surgeon to the Manchester corporation, for the other quarters he said that he had not got them and that he bought the meat from a man on the road. The quantity destroyed was 6½ hundredweights. Dr. Martin said that the meat was dropsical, of an unhealthy pale red colour, and there was extensive general tuberculosis. This meat had not been to the corporation abattoirs where it would have been seen. It seems that this man Longden is a "alnk butcher" in rather an extensive way, for the sanitary inspector to the Bucklow district council, Cheshire, found at the quiet village of Mobberley a building used as an unlicensed slaughter-house by Longden in which were four sides of beasts which were destroyed as unfit for food. The position of this man seems to be well known, one of the police sergeants saying that he did an extensive business in the district. This does not speak well for the farmers who have dealings with him. Mr. Yates characterised the case as a very bad one which a fine would not meet. The chief offender was sent to prison for three months, the second defendant, a brother, for one month, and the third man, against whom there was no evidence that he had dressed the meat, was discharged. It is satisfactory that at last a case has been followed up and that the offenders have gone to prison instead of merely paying a trifling fine.

Cotton Districts Convalescent Fund.

It seems a far cry to the days of the American Civil War and the cotton famine resulting from it that caused such widespread distress through the manufacturing districts of Lancashire. But a meeting of the governors of the Cotton Districts Convalescent Fund held on Jan. 25th reminds us of what was not only a gigantic and most beneficent scheme, but one which was carried through with enduring energy and devoted patience. Many of the chief actors are gone but some remain, among whom is Earl Egerton of Tatton, whose resignation of the chairmanship of the board was received with much regret. The Earl of Derby was elected chairman for 1907. When the cotton famine was over the funds remaining were devoted in great part to the convalescent hospitals of Southport and Buxton, and an active interest is taken in those institutions. During the past year 2933 patients were sent to these hospitals at a cost of £5219, against 2896 sent at a cost of £5506 in the previous year.

Jan. 29th.

LEEDS.

(FROM OUR OWN CORRESPONDENT.)

Appointments at the General Infirmary.

At a meeting of the governors specially summoned for the purpose Mr. W. H. Brown, who recently resigned his position as surgeon to the institution, was elected an honorary consulting surgeon. This position entitles the holder of it to the use of six beds in the infirmary and is one which

falls without special election to those who have served the institution as members of the full staff for a period of 20 years, or who while acting in that capacity have attained the age of 60 years. As Mr. Brown's resignation was determined by ill-health it required a special meeting of the governors to entitle him to his new post, and that they have carried out the recommendation of the board in making the election is a source of pleasure to his colleagues who may confidently hope that his health will improve with his relief from the more strenuous of his infirmary duties. Mr. Joseph F. Dobson was on the same day elected honorary assistant surgeon to the infirmary. His appointment will cause a vacancy in the position of honorary assistant surgeon in charge of the two semi-convalescent hospitals which he has held for about two years. At a meeting of the faculty the following resident appointments were made: Mr. J. B. F. Wilson was appointed house physician to Dr. T. W. Griffith, Dr. M. G. L. Walker, house surgeon to Mr. E. Ward, and Dr. F. G. Dobson to Mr. R. L. Knaggs.

Appointments at the University.

Some time ago the increase in the amount of bacteriological work, which was carried out at the medical school on behalf of the various county councils, necessitated the appointment of an additional demonstrator most of whose work was in that department. Dr. R. D. Smedley who held the position having been appointed demonstrator of pathology and bacteriology in the University of Sheffield, the council has appointed Dr. Myer Ooplans as his successor, who has begun his duties as demonstrator of bacteriology. The council has also appointed Dr. Charles Porter as honorary demonstrator of public health. Dr. Porter holds the position of assistant medical officer of health of the city of Leeds. Dr. J. S. Cameron is, of course, professor of public health in the University, as well as medical officer of health of the city. The easy coördination of work which arises from this enables great facilities to be put in the way of medical students or those attending classes for the Diploma of Public Health for the study of matters dealing with municipal sanitation.

Meeting of Sanitary Inspectors.

Under the chairmanship of Mr. T. Pridgin Teale, the President, an interesting meeting of the north-eastern centre of the Sanitary Inspectors' Association has lately been held in Leeds. Mr. F. S. Sharp read an instructive paper on Ancient and Modern Methods of Constructing and Testing Drains. He laid it down as an important principle that drains should be of the smallest diameter that was consistent with the amount of work which they had to do and to secure thorough scouring there should be a proper fall. He was a warm advocate of the water-test for drains in all cases where it could be carried out thoroughly. The President referred to times well within his recollection when the system of drainage in Leeds involved the lifting up of a flag in the cellar kitchen and the removal of black sludge in buckets. The drains were of the old-fashioned brick-built character. He referred to the recent excavations in Crete, where in what was taken to be the Palace of Minos terra-cotta pipes with flanges were found, which seemed to indicate that the water-carriage system had been employed so long as 4000 years ago and that sanitary matters were in this respect in a more advanced condition than they were at Windsor Castle at the beginning of the last century. Mr. Teale also said he was glad to learn that the building clauses committee and the sanitary committee of Leeds now worked in harmony and that their work was coördinated. The writer of this paragraph has some experience of the former state of affairs and the result of this was that in his house a soil pipe of some three and a half inches diameter was fitted into a drain pipe of six inches instead of into one of four or four and a half inches in diameter with, as a consequence, a joint which was imperfect.

Overcrowding at the Workhouse.

During the last 20 years the amount of pauperism in the Leeds union has steadily increased. In 1887 the returns showed that on Jan. 1st the total number of inmates of the workhouse and of the infirmary attached thereto was 874—383 in the former and 491 in the latter. The numbers for Jan. 1st of the present year are respectively 832 and 838, a total of 1670, an increase of nearly 100 per cent., and an increase out of all proportion, of course, to that of the population. There are

Handbook of Obstetrics embodying his personal experience. More recently he published a treatise upon midwifery in collaboration with his pupil, Dr. Demelin, and finally he wrote a most interesting book "The Nursing," in which may be found an account of his admirable and patient researches into the hygiene and treatment of infants. An English translation of this work has just appeared. Professor Budin was, with M. Strauss, the founder of the League against Infantile Mortality, and was the first to institute consultations for nurslings (*consultations de nourrissons*) in the hospitals. He has left behind him the reputation of an indefatigable, scrupulous, and patient worker, and an admirable professor of his science. His rectitude, the soundness of his teaching, and his deep sympathy with and tenderness towards his patients combined to make him one of the best respected and loved professors of his day.

Jan. 28th.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Medical Practice Abroad.

Dr. J. Schwalbe, the editor of the *Deutsche Medizinische Wochenschrift*, has recently drawn attention to the fact that medical practice abroad tends to become more and more difficult for German medical men in consequence of restrictions imposed by foreign legislation. In the United States of America, for instance, 20 years ago the majority of the States admitted foreign practitioners without an examination and almost without any formalities. At present, however, an examination is required nearly everywhere in America and a licence must be obtained. In the French part of the Riviera where formerly medical men of all countries resided, to the great advantage of foreign visitors, the strict application of the French law of 1892 has induced the foreign medical men to leave with the exception of a few who were there previously to the enactment of the law. Also in Italy the Santini party endeavour to deprive foreign practitioners of the right which they have hitherto had of practising among their countrymen. More than 100 German medical men residing in the Riviera would thus be obliged either to obtain Italian qualifications or to give up their practices. Dr. Schwalbe therefore proposes to mitigate these drawbacks by international treaties of reciprocity in which the states concerned would agree to a mutual recognition of diplomas. Similar conventions exist in certain Swiss cantons and between Italy and England. Moreover, Germany and some of its neighbouring countries also recognise the diplomas of medical men residing in frontier towns, but of course only for practice in the frontier districts. It has been argued that if such treaties were concluded foreign medical men would be induced to settle in Germany, but this argument is obviously erroneous. Apart from the difficulty of the language the overcrowding of the profession in Germany would certainly prevent foreign medical men from seeking their livelihood there. It would be only in some watering-places and health resorts frequented by foreign patients that foreign medical men would have a chance of prospering to the detriment of the German local practitioners, but this they are at the present time quite at liberty to attempt under existing legislation, provided always that they are careful not to assume a medical title by which patients may be induced to believe that they are duly qualified in Germany. The suggestion of Dr. Schwalbe that Germany should follow the example afforded by the arrangement already made between Italy and Great Britain is therefore very reasonable.

Insanity in the Russian Army during the Russo-Japanese War.

In the *Russische Medizinische Rundschau*, a medical journal in the German language, edited by Russian medical men and issued in Berlin, a paper by Dr. Borischpolski deals with the subject of insanity among the Russians engaged in the war with Japan. Dr. Borischpolski, who was attached to a military hospital at Harbin, blames the inadequacy of the preparations made by the Russian war department for the care of the sick and wounded soldiers. Owing to the absence of an effective system of organisation medical officers sent from Russia to the seat of war had to stay for months at Harbin or Chaborovsk without occupation. After the great battles five or six army medical officers had

sometimes to attend 700 wounded, whilst a few miles further away there were numerous surgeons with little or nothing to do. The possibility of the occurrence of mental diseases was never considered, although numerous cases of insanity had been observed during the military operations in China. At the beginning of the war the insane were kept in the military hospitals among the other soldiers and were under the care of medical men without special knowledge of mental diseases. Insane officers were, for instance, placed in the syphilitic department of the hospital. In course of time the number of insane increased so much that in the summer of 1904 two houses were specially fitted up for them, one house for officers and the other for soldiers, where the patients were better attended and cared for than in the general hospitals. Until December, 1904, when the care of the insane was left to the Russian Red Cross Society, 111 officers and 289 soldiers were conveyed to the provisional lunatic asylum. As there was room only for 30 patients they had to be sent home very soon, whilst quiet cases were conveyed to other hospitals. Until December, 1904, there were 263 patients sent home in batches of 30 to 35 men. The patients travelled on the railway at first in ordinary passenger carriages but afterwards in carriages fitted up with bars and gratings for the conveyance of prisoners. The journey as far as Irkutsk, the capital of Siberia, required from three to four weeks. A statistical table shows that alcoholic psychoses and progressive paralysis were the more frequent mental diseases in the army; also traumatic psychosis, epilepsy, dementia, and hysteria were frequent among the lunatics.

The Congress of Internal Medicine.

The German Congress of Internal Medicine will meet this year at Wiesbaden, Professor von Leyden being in the chair. The official subject of discussion is the treatment of neuralgia and Professor Schultze of Bonn will read the introductory paper. Other subjects already announced are: Chronic Poisoning by Manganates, by Professor Jaksch of Prague; the Present State of Percussion of the Heart, by Professor Trempel of Frankfurt; and the Coronary Circulation and the Heart Muscle, by Dr. Hirsch and Dr. Spalteholz of Leipzig. The Congress will meet from April 15th to 18th.

Jan. 28th.

ITALY.

(FROM OUR OWN CORRESPONDENT.)

Foreign Medicines.

THE pharmaceutical interest outside Italy is directly struck at by an ordinance just issued from the Direzione Generale di Sanità prohibiting the introduction into the Italian kingdom of all medicines prepared in foreign countries. The motive of this measure is officially stated to be the "protection of public hygiene" and the "desire to obtain for our own products of a similar kind a more favoured treatment abroad." This prohibition, the ordinance hastens to add, is "not absolute but relative," since medicines of foreign preparation will be allowed to come into Italy if the Direzione di Sanità shall have previously been notified as to their composition. In terms of this proviso the Customs houses at the frontier will have the right to examine the medicine or medicines seeking a market in Italy. The result would seem to be that, having obtained from the Italian Government "il brevetto di privativa" (certificate of special privilege), the foreign pharmacist may be relieved of any further obligation to disclose the composition of his medicines if sold in Italy. In any case the preliminaries cannot but be vexatious, if not costly; indeed, the ordinance is of a piece with the attempt, so often renewed of late years, to deprive the non-Italian, particularly the English-speaking, practitioner of the right to exercise his profession in Italy unless provided with an Italian diploma.

Honours to Camillo Golgi.

On Jan. 23rd the Aula Magna of the University of Pavia was thronged with students, past and present, the academic authorities, the magistracy, communal and municipal, and representatives of the various civic interests to witness the bestowal on Professor Golgi of an illuminated parchment setting forth the congratulations of his pupils on his having been awarded the Nobel Prize for pathological research.

Dublin college for Catholics are to be undenominational in their constitution. The scheme, which seems on paper a bold and broad-minded one, has on the whole been received favourably, but, of course, everything will depend on the details, such as the functions and powers of the Senate and the amount of autonomy enjoyed by the federated colleges.

The Cork Sanatorium Project.

The Cork sanatorium board decided on selecting a site at a place called Myshall, about 12 miles from Cork. The Tullip river, which is a tributary of the Lee, runs through the grounds. One of the city medical men wrote to the newspapers pointing out that the Cork water-supply is derived from the Lee and that if the patients at the sanatorium carelessly expectorated into the river there would be danger that consumption would be spread among the citizens. Professor E. J. McWeeney, bacteriologist, Dublin, wrote in reply, practically asserting that there would be no such danger. The corporation became alarmed and appeared by counsel at the Local Government Board inquiry held last week. The proceedings extended over four days and attracted considerable attention. Dr. O. Theodore Williams of London gave evidence expressing general approval of the site. Mr. Fairley, engineer, of London, described the methods which it was proposed to adopt for the disposal of the sewage and said that the effluent might be safely discharged into the Tullip river. Professor McWeeney, in his evidence, stated there was no danger to be apprehended from the sewage. He did not think there was much chance of the citizens of Cork being injuriously affected by the patients expectorating into the river. In the course of cross-examination he stated that tubercle bacilli can live in river water, but not for an unlimited time, and that it would be highly dangerous to drink a tumbler of water into which a consumptive patient had expectorated. Dr. A. E. Moore, lecturer on bacteriology at the Queen's College, Cork, in the course of his examination said he disapproved of the effluent being conveyed into the river and pointed out how the arrangements for purifying the sewage might break down with the result that intestinal tubercle bacilli could find their way into the river. He considered the fact of the patients expectorating into the river would be a distinct source of danger. Dr. A. R. Parsons of Dublin, visiting physician to the Newcastle Sanatorium, and Mr. F. K. Edinger, superintendent of Ootswold Sanatorium, considered the site unsuitable for a sanatorium. Amongst other witnesses examined were three Cork medical men and two of the Cork engineers. The value of sanatorium treatment was discussed. There was a very strong bar and from a scientific point of view the proceedings were extremely interesting. The decision of the Local Government Board is awaited with some apprehension and the citizens, apart entirely from the question of danger, regard with repugnance the idea of establishing a consumptive sanatorium on the bank of a river which provides their water-supply. It is believed that if the decision of the Local Government Board should be in favour of the Myshall site the Cork corporation will appeal to a higher tribunal.

Jan. 30th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Treatment of Pre-Sclerosis.

M. Huchard made a communication upon the above subject to the Academy of Medicine on Jan. 15th, and the occasion was notable not only on account of the importance of the subject and the position of the reader of the paper but also because it gave rise to a most interesting discussion among those leaders of the French medical profession who have studied the subject. M. Huchard began by saying that by the name pre-sclerosis he meant the clinical period which is characterised by arterial hypertension more or less pronounced, without, however, any definite arterial lesion. Hypertension preceded vascular lesions and was not consecutive to them. It is caused above all by poisons derived from the digestive system which act upon the coats of the vessels, upon the medulla which is the regulator of the heart, and also upon the kidney, which the passage of these poisons irritates so that it becomes less permeable than it ought to be. Hypertension thus having come into existence the arteries take on

a certain compensatory hypertrophy, as does every organ which is forced to do greater work than the normal. Arterial sclerosis is thus brought about which is extremely difficult to cure, although the stage of pre-sclerosis is very accessible to treatment. Among agents for lowering the arterial tension M. Huchard pointed out that the chief were the nitrites and the serum of milk or the lacto-serum of Blondel, massage, muscular exercises, carbonic acid baths, the "cure" carried out at Bourbon-Lancy, and the use of high-frequency currents, but these last, said M. Huchard, apparently only bring about a temporary improvement. Finally, the diet must be carefully attended to. M. Lancereaux, M. Hayem, and M. Ohantemesse could not altogether agree with M. Huchard's opinion upon the mechanism of the production of arterial sclerosis, for they considered that it was very often anterior to the hypertension. M. Huchard replied that if the arterial lesions existed at the commencement of the hypertension they were only extremely slight and impossible to diagnose in the living body. M. Albert Robin said that he was able to confirm on all points the researches of M. Huchard who, he considered, had brought about a veritable revolution in the treatment of morbus cordis and diseases of the blood-vessels, and the effects of these researches were much more widespread than was generally thought. Certain cases of dyspepsia, for instance, occasionally present crises of hypertension and the dyspepsia can only be cured by treating the hypertension. Moreover, added M. Robin, the question whether the arterial lesions are cause or effect matters very little. The essential point is that the treatment advocated by M. Huchard incontestably causes the disappearance of the hypertension, and with the disappearance of this the arterial sclerosis also disappears.

Hygiene and the Prevention of the Freezing of Drinking Water.

General Jourdy, the new Governor of Verdun, having in his inspection of barracks noticed that the standpipes were covered up with manure to prevent them from freezing, came to the conclusion that there was great danger of contamination of the water from this practice. He has therefore issued an order that only clean materials of vegetable or animal origin shall be used for the purpose, such as straw, sawdust, shavings, rags, or hair, which must previously to being used be conveyed to the hospital, there to be sterilised.

Wound of the Heart by a Foil; Suture; Recovery.

At a meeting of the Society of Surgery held on Jan. 9th M. Quénu, on behalf of M. Baudet, read the account of the case of a man, aged 25 years, who was wounded in the fifth left intercostal space by a thrust with a foil. M. Baudet turned up a flap of the thoracic wall and found a small wound in the heart. This was sutured and the flap being replaced the wound was dressed without any drainage. At the end of 12 days the patient was well.

The Treatment of Tuberculosis by Marmorek's Serum.

At a meeting of the Academy of Medicine held on Jan. 15th M. Charles Monod gave an account of some researches which had been carried on since 1903 by various physicians, mainly in foreign countries, upon the treatment of tuberculosis by Marmorek's serum. It appeared from the results of the inquiry that the serum at any rate did no harm and that in many cases good had resulted from its use, especially in cases of surgical tuberculosis. The most favourable reports had been sent in by Lewin in pulmonary tuberculosis and by Hoffa and van Hueller in surgical tuberculosis.

Death of Professor Budin.

Professor Budin died on Jan. 22nd at Marseilles, succumbing to an attack of pneumonia contracted while visiting that town for a conference of the League against Infantile Mortality, of which body he was the president. He was born at Enancourt-le Sec (Oise) on Nov. 9th, 1846, and was therefore just over 60 years of age. In 1871 he became interne des hôpitaux, Paris, and nine years later agrégé to the Faculty of Medicine in the University. In 1888 he was elected to the Academy of Medicine, and in 1898 he succeeded his distinguished master, Professor Tarnier, as professor of clinical obstetrics in the University. His scientific, practical, and literary work has been very inclusive in the direction of midwifery and the care of the newly born. He completed Tarnier's classic "Traité des Accouchements," and in 1886 published an important

In Toronto he attended meetings of the medical profession on three occasions, on one of which at the Ontario Medical Library he unveiled a portrait of the late Dr. James E. Graham, formerly professor of medicine in the University of Toronto and one of the most distinguished physicians whom this continent has ever produced. This portrait was a present to the library by the widow and the son, Dr. J. S. Graham of Toronto.

The Toronto Board of Trade and Tuberculosis.

The Toronto Board of Trade has protested to the Government of the Dominion of Canada against admitting into Canada immigrants already the victims of tuberculosis, stating that the immigration inspectors are lax in their duties. The board bases its charge on the facts as secured from the Muskoka Free Hospital for Consumptives and from the Toronto Free Hospital for Consumptives at Weston, Ontario. At the former institution, out of 243 patients treated in the last hospital year, 83, or one-third, were of foreign birth, and an analysis of these individuals' cases shows that a goodly proportion of these left their homes already the victims of the disease. The board requests the Government that steps should be immediately taken to prevent embarkation for Canada of any emigrants suffering from any pulmonary or contagious diseases.

The Canadian Militia Medical Service.

Lieutenant-Colonel G. Carleton Jones, M.D. (Halifax, Nova Scotia), has been appointed Director-General of the Army Medical Service of the Canadian Militia at Ottawa, to succeed Lieutenant-Colonel Fiset who has been made deputy minister of militia. Lieutenant-Colonel H. S. Birkett, M.D., A.M.O. (Montreal), has been appointed principal medical officer of the Quebec Command, vice Dr. O. W. Wilson resigned. Lieutenant-Colonel and Hon. Colonel George Stirling Ryerson, M.D. (Toronto), has been transferred to the reserve of officers. Lieutenant-Colonel A. B. Osborne, M.D. (Hamilton, Ontario), has also been transferred to the reserve of officers. Major A. N. Hayes, M.D. (Sarnia, Ontario), becomes lieutenant-colonel, vice Colonel Ryerson transferred.

The Toronto Provincial Hospital for the Insane.

Dr. Charles K. Clarke, medical superintendent of the Toronto Provincial Hospital for the Insane, has been instrumental in securing the appointment by the Ontario Government of a resident pathologist to the institution over which he presides. The appointed officer, who will devote all his time to the work in this institution, is Dr. J. H. Fitzgerald, a graduate of recent date in the University of Toronto, who for the past two years has been pursuing special studies in psychiatry in Johns Hopkins Hospital, Baltimore, and other hospitals of the United States. Dr. Clarke has made a distinct advance in this subject in Canada by securing this appointment.

The Deportation of Insane from Ontario.

The deportation of insane from the province of Ontario—that is, of those who have lived for less than two years in the province—is being actively conducted under the department of the Inspector of the Provincial Hospitals for the Insane. The Dominion Government Immigration Act provides for this and the province is taking advantage of the provisions of the Act. In the case of the English immigrants the correspondence and technical work are conducted through Canada's High Commissioner, Lord Strathcona. During the three months ending with November one was returned to Russia, two were returned to the United States, and five to England. There were then four awaiting return to England and one to Sweden. It is estimated that the province saves \$2000 by each deportation.

Hospital Abuse in Montreal.

Now that the hospitals of Montreal are so constantly filled to overflowing hospital abuse seems to be more glaring. According to the medical men the Montreal General Hospital is the one hospital in that city which suffers most from hospital abuse. Day after day women drive up to the doors of the out-patient departments in cabs to receive free treatment at the hands of the physicians in attendance. It is quite plain that they could as well afford to pay for their medical advice and medicines as for their cabs, furs, silk clothes, and smart bonnets.

Jan. 21th.

Obituary.

JOHN NEWNHAM WINTER, M.R.C.S. ENG.,
M. AND L.S.A.

THE death of Mr. John Newnham Winter on Jan. 18th at his residence near Kew Gardens after a few days' illness from influenza removes one who was for many years extremely well known to the profession at Brighton. Educated at a private school at Winchester, of a type now practically extinct, he received his medical training at Guy's Hospital, qualifying as a Member of the Royal College of Surgeons of England and a Licentiate of the Society of Apothecaries in the year 1853. From 1853 to 1855 he was house surgeon at the Sussex County Hospital at Brighton. After a brief journey to Egypt and Palestine he joined his father, the late Mr. Thomas Bradbury Winter, in practice at Brighton. Here he rapidly acquired a very extensive practice and for a great many years there were few more familiar figures among the medical men of the town. For several years he was in partnership with his brother-in-law, the late Mr. F. W. Salzmann. Of an extremely retiring disposition, he shrank from all public office and he was too busy to discharge the duties incidental to professional appointments, but at the time of his death he was honorary consulting surgeon to the Brighton and Hove Hospital for Women and a few years ago he was elected a member of the Society of Apothecaries and frequently attended the meetings of the Court. On his relinquishing practice in 1900, at the age of 70 years, he settled at Kew, no doubt determined in his choice by his devotion to flowers and gardening. He was a recognised authority on filmy ferns and was frequently consulted by those interested in such subjects.

His funeral at Brighton on Jan. 21st produced many testimonies to the respect in which he was universally held.

ALEXANDER PEDDIE, M.D. EDIN., F.R.C.P. EDIN.

By the death of Dr. Alexander Peddie a venerable link with the past has been removed from the medical life of Edinburgh and of Scotland. Born in 1810 he was in his ninety-seventh year. He was the son of the Rev. Dr. James Peddie who was minister of the United Associate Congregation in Bristo-street, Edinburgh, for 62 years. He died in his house in Rutland-street, Edinburgh, on Jan. 19th. Until quite recently he could from time to time be seen in the streets at the west-end of Edinburgh, where his erect figure and white hair hardly revealed his age. His advanced age has naturally turned men's minds to think of all that the world has passed through in the span of one man's life, while to the medical man it is little short of incredible that there is so much difference between the profession of to-day and of 90 years ago, and yet Dr. Peddie lived and worked during the greater charges which signalled the last half of the nineteenth century. Dr. Peddie began his medical life by becoming an apprentice to Professor James Syme in November, 1830; in 1835 he became a Licentiate of the Royal College of Surgeons of Edinburgh and took the degree of M.D. at the University of the same city. In 1845 he was admitted F.R.C.P. Edin. The autumn and winter of 1835 were spent on the continent in travel and study. On his return to Edinburgh he began general practice. For many years, first in conjunction with Dr. John Brown and Dr. Cornwall and then alone, he carried on a hospital and dispensary at Minto House when Syme gave it up on being appointed to the staff of the Royal Infirmary. His contributions to medicine, written in the earlier years of his career, were published in the *Edinburgh Medical Journal* and it is interesting to note that in 1854 he published a paper suggesting that inebriety was a manifestation of insanity and that he treated delirium tremens without stimulants or opiates. He dealt in another paper with Legalised Arrangements for the Treatment of Dipomania. He was regarded as such an authority on the question that he on two different occasions gave evidence before committees investigating the question. In this he was much in advance of his time. As early as 1845 he wrote on the "Contagious Nature of Puerperal Fever" and in 1849 he was advocating the establishment of a hospital for sick children. He thus showed himself to be possessed of some of the higher faculties of the physician which might have still further enriched the medical literature of Edinburgh, but he devoted his time and

Signed by the students in other faculties besides the members of his class, the inscription runs as follows:—

Camillo Golgi—culus nomen—ob mirabilis scientiæ artisque medicæ inventa atque incrementa—lampadem—summa laudibus honoribusque ubique concelebratam—nuperime præsum nobilissimum—ollum ab Alfreda Nobel scientiæ ac merito propositum—decoravit, provexit, adauxit—tauto viro—qui sic et ipsius et civitatis et patriæ—famam ac decus ære perennius—coram omnibus nationibus confirmavit asseruitque—Atheniæ Ticinensis Alumni—uno animo una voce—gaudentes gratulantes—honoris memoriæque causa—tabulam membranaceam arte depictam—magnæ admirationis parvum documentum dictam consecratamque—voverunt.

[To Camillo Golgi, whose name, long celebrated universally with the highest praise and honour for the marvellous discoveries with which he has enriched the science and art of medicine, and which, quite recently, the prize offered by Alfred Nobel for scientific merit has adorned, promoted, and enhanced—to the distinguished man who, in the eyes of all nations, has thus confirmed and vindicated for his city and country a fame and a glory more enduring than brass, the students of the University of Pavia, with one mind and voice, have, with joy and congratulation, and in perpetuation of the honour, wished solemnly to dedicate this artistically illuminated parchment as a humble proof of their profound admiration.] The design and execution of the parchment, I may add, are due to Professor Provini, well known for his skill in that *métier*, and the inscription is from the pen of Pietro Rasi, the eminent occupant of the Latin chair in the Lombard University.

The Red Cross at the Pontine Marshes.

THE LANCET has from time to time taken cognisance of the service organised by the Red Cross in the Roman Campagna—a service which has already gone far to minimise the death-rate from malaria in that region—a service, moreover, which is now, on the initiation of the Prefect, to be extended farther south, to the deadly level of the Palude Pontina. On Tuesday next (29th inst.) he will confer in Rome with the communes of that "zona malarica" from Velletri to Tarracina, the meeting being further reinforced by the Società per gli Studi della Malaria, by the Conforzio Idrantico Pontino, by representatives of the agrarian schools, and by other bodies interested, so as, in concert with the Red Cross, "to institute a permanent sanitary service" in that notorious and much-neglected "fever preserve." So constituted and equipped, with the admirable record of its "campagna antimalarica" to guide and encourage it, the "Red Cross Extension" may ere long be expected to reduce the all too heavy returns of disease and death on a seaboard held, from a remote antiquity, in the worst hygienic repute.

Jan. 25th.

CONSTANTINOPLE.

(FROM OUR OWN CORRESPONDENT.)

A New Hospital.

THE Ottoman Government has decided to build a new hospital in Stambul as an annexe to the Hamidié Hospital at Shishli. The new building will be provided with a special section for midwifery and gynecological cases. I am informed that the Sultan intends to give a substantial sum from his private purse to enable the erection of the annexe to be begun as soon as possible.

Adulteration of Foodstuffs.

It has been found that macaroni and other similar articles of alimentation imported into Turkey are almost always adulterated. Chemical analysis undertaken by the laboratory of the Custom House reports that a certain kind of macaroni imported from Italy is coloured with dyes which are prejudicial to health. It has therefore been decided strictly to prohibit any further importation of the sophisticated article and to confiscate all which is already imported and offered for sale at the *bacals* (grocers).

The Water supply of Damascus.

The present water-supply of the city of Damascus is far from being satisfactory. Damascus is provided with water from a distant source which, before it arrives for distribution at Damascus, runs through plains, valleys, and villages, and becomes in its course contaminated by various impurities. Those settled around the source and the course of the water-supply throw into it all imaginable refuse. In the

city itself the water receives new impurities in passing from house to house, and the cause of the prevalence in Damascus of typhoid fever requires no further explanation. It is intended now to remedy this dangerous state of affairs. The same source will be used, which is in itself perfectly pure, but a complete system of iron tubes will be provided and other general measures will be taken in order to make contamination impossible.

Disastrous Inundations.

The local newspapers have given full details of the terrible floods in the vilayet Aydin. Immense spaces have been transformed into lakes, causing incalculable damage. Villages have been destroyed, many people have perished, and entire flocks of sheep and cattle have been drowned. The distress of the panic-stricken population was indescribable. It is estimated approximately that the material losses suffered by the surroundings of the locality of Sarouhan alone amount to 150,000 Turkish liras (one lira=18 shillings). The local authorities of the vilayet have done all in their power to lessen the sufferings of the population. Help has been sent from Constantinople. In Smyrna a special commission has been instituted, under the presidency of the Governor-General of the vilayet, with the purpose of collecting subscriptions for the calamity-stricken population and similar collections have been made in other important centres of the province.

The "Mangal."

In most of the houses in Constantinople as well as in other cities of Turkey heating in winter is done by means of the so-called *mangal*. This consists principally of a receptacle for burning charcoal. A *mangal* may be nothing else than such a simple brass or iron receptacle or may be quite an artistic and expensive article of most rare and valuable workmanship. The charcoal is first thoroughly burned through, and when it no longer emits any flame or odour the *mangal* is brought into the room for purposes of heating. Sometimes it happens that proper attention is not paid to the burning charcoal with not infrequent fatal results.

Jan. 19th.

CANADA.

(FROM OUR OWN CORRESPONDENT.)

Typhoid Fever in Ontario.

DURING the month of November, 1906, there was an abnormal prevalence of typhoid fever in the province of Ontario. As regards its chief city, Toronto, the intake pipe to the city reservoir runs on the bed of Toronto Bay, into which all the sewage is discharged, but although this pipe had a break and the drinking water was contaminated there was not much of the disease in the city. The prompt action of the medical health officer and the continuous advertisement of "boil the water," as well as the acceptance of the advice on the part of the people, cut short any chance of an epidemic. Throughout the entire province of Ontario about 1500 cases of the disease were treated and 113 deaths from it were recorded. Following immediately the break in the conduit in Toronto Bay the city held its annual municipal elections, but the ratepayers refused authority to the city council to deal effectively one way or another with the sewage problem, voting against the proposed by-law for a trunk sewer.

Typhoid Fever in Montreal.

In the city of Montreal and the immediate surrounding municipalities there are at the present time nearly 1000 cases of typhoid fever, and two young Montreal practitioners have succumbed to the disease. Dr. John D. Cameron, who graduated from McGill University in 1893, died on Jan. 4th from the disease at the age of 38 years. He was at the time of his death assistant gynecologist to the Montreal General Hospital. The other victim was Dr. G. A. L. Payne, aged 27 years, who had only graduated from McGill University last year. All the hospitals in Montreal are filled. The Quebec board of health, through its secretary, Dr. E. Pelletier, will investigate and make a report on the outbreak.

Professor Osler's Visit.

During the latter part of December, 1906, Professor W. Osler with his family was visiting in Toronto and Montreal.

experiment ought to be a distinct success. The *Annals* will be edited by Professor Ronald Ross, with whose work Dr. J. W. W. Stephens, Dr. John L. Todd, Dr. H. Wolferstan Thomas, Dr. Anton Brühl, Mr. Robert Newstead, and Sir Robert W. Boyce will be associated. The subscription (10s. 6d. per annum, post free) can be forwarded at once to the secretary of the Liverpool School of Tropical Medicine, B 10, Exchange buildings, Liverpool.—We reviewed the first edition of MacCabe's "War with Disease" in our issue of Jan. 17th. A second and enlarged edition in a cloth cover has now been published at 1s. net by Messrs. Baillière, Tindall, and Cox. This edition is dedicated, by permission, to H.R.H. the Duke of Connaught.—Messrs. Methuen are issuing a work on the alcohol question entitled "The Drink Problem in its Medico-Sociological Aspects," and edited by T. N. Kelyack, M.D. Vict., M.R.C.P. Lond., honorary secretary of the Society for the Study of Inebriety.

ROYAL UNITED HOSPITAL, BATH.—A public meeting was held at the Guildhall, Bath, on Jan. 22nd, under the presidency of the Mayor, to consider the financial position of the Royal United Hospital and the best means of reducing the debt of £5000 which exists on the institution. The Mayor will make an effort to wipe off the debt during his year of office and stated that he had already received several subscriptions for this purpose. After some discussion the meeting pledged itself to support the mayor in his admirable determination to place the Royal United Hospital on a sound financial basis.

FRIENDLY SOCIETIES AND THEIR MEDICAL OFFICERS.—Replying to the toast of "The Medical Officer" at the annual dinner of the Pioneer Benefit Society, held recently at Warminster, Wiltshire, Mr. F. I. Flower, M.R.C.S. Eng., said that although both the social condition of working men and their wages had been raised the medical officers to working men's clubs were very inadequately remunerated. He thought that in all clubs there should be special fees for cases of fractured limbs and operations and that in time it would have to be so.

UNREGISTERED MIDWIVES AT TRURO.—An inquiry was held at Truro, Cornwall, on Jan. 24th relative to the death of a newly born infant. The mother of the child had been attended by an uncertified midwife. The coroner (Mr. E. Carlyon) said that there was no suspicion of foul play, but he warned the midwife against continuing to act as such. Mr. Carlyon added that of all the midwives practising in Truro only two were registered. The jury eventually decided "that the attention of the Cornwall county council should be called to the fact that there were women practising midwifery in Truro without certificates."

THE NEWLY UNITED CLINICAL SCHOOL OF THE UNIVERSITY OF LIVERPOOL.—The first annual dinner of the united clinical school in connexion with the University of Liverpool was held at the Adelphi Hotel, Liverpool, on Jan. 24th. Sir James Barr, the chairman of the united clinical school, presided, and there was a large gathering of members of the profession and leading citizens. Prior to October last the united hospitals clinical school, comprising the David Lewis Northern Hospital, the Royal Southern Hospital and the Stanley Hospital, competed in friendly rivalry with the Royal Infirmary in training medical students in clinical work. Largely owing to the tactful efforts of Dr. T. R. Bradshaw, as gracefully acknowledged in his speech by Sir James Barr, a union has been effected by which one large and greatly strengthened clinical school is provided for the medical students of the University of Liverpool. Professor A. M. Paterson, in proposing one of the toasts, said that the union of the hospitals for the purpose of clinical teaching suggested to him and others the establishment of one central local authority for the administration and control of all the hospitals—general, civic, and Poor-law. Objection was taken to this suggestion by Sir Robert Hampson, the President of the Stanley Hospital, on the ground that it might promote "central control and officialism," and by Mr. Ralph Brocklebank, the chairman of the Royal Infirmary, who deprecated any step that would tend to bring the voluntary hospitals on to the rates. However, it ought not to be impracticable to devise some scheme whereby the individuality of the general hospitals should be maintained and at the same time the advantages of combination might also be attained.

Heft XVIII.) Price M.6.

energies to a large family practice, and in this work few men won more confidence and affection from their patients than Dr. Peddie received. He was, however, possessed of varied gifts; he was an enthusiastic musician and a keen sportsman, his special delight being salmon fishing. His last salmon was caught when he was 84 years of age. He belonged to the United Presbyterian Church for many years and was present when that body united with the Free Church in 1900.

He has been widely known as the intimate friend of Dr. John Brown, the author of "Rab and His Friends." In 1890, when President of the Edinburgh Harveian Society, his oration was devoted to reminiscences of his old friend and this oration was amplified into a larger biographical sketch. Dr. Peddie was buried in Warriston Cemetery, Edinburgh, on Jan. 23rd, the funeral being attended by the Presidents of the Edinburgh Royal Colleges of Physicians and of Surgeons and many other members of the medical profession. Mrs. Peddie predeceased her husband by a few years.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated:—

Surgery.—H. A. Fenton (Section II.), St. Mary's Hospital; O. P. N. Pearn (Sections I. and II.), Westminster Hospital; D. E. G. Pottinger (Sections I. and II.), Edinburgh; and S. Singh (Sections I. and II.), Glasgow.

Medicine.—M. L. Ford (Section I.), London Hospital; D. B. O. Pottinger (Section II.), Edinburgh; O. S. Spencer (Sections I. and II.), Manchester; A. R. Wade (Section II.), St. Bartholomew's Hospital; and C. J. Wolfe (Section I.), Edinburgh and London Hospital.

Midwifery.—O. F. Curtis, Manchester; and A. C. J. Elwin and J. F. McQueen, King's College Hospital.

The diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery: O. P. N. Pearn and D. B. O. Pottinger.

UNIVERSITY OF OXFORD.—In a congregation held on Jan. 24th the following degrees were conferred:—

B.M., B.Ch.—H. G. F. Spurrell, Merton College; H. A. Philpot, New College; H. R. Ransbotham, Brasenose College; B. R. A. Batt, Trinity College; C. Beards, Jesus College; and H. H. Carleton, Keble College.

D.Sc.—G. F. H. Smith, New College.

FOREIGN UNIVERSITY INTELLIGENCE.

Baile: Dr. Oppikofer has been recognised as *privat docent* of Otolaryngology. **Bonn:** The title of Professor has been conferred upon Dr. Karl Grouven, *privat docent* of Dermatology; Dr. Eduard Hummelsheim, *privat docent* of Ophthalmology; and Dr. Julius Strassburger, *privat docent* of Internal Medicine. **Erlangen:** Dr. Spaeth, a well-known writer on medical chemistry, has been granted the title of Professor. **Freiburg:** Dr. W. Spielmeier has been recognised as *privat docent* of Mental Diseases. **Halle:** Dr. Louis Wullstein, *privat docent* of Surgery, has been granted the title of Professor. **Harvard:** Dr. Walter B. Cannon has been appointed Professor of Physiology. **Heidelberg:** Dr. Franz Fleschler has been recognised as *privat docent* of Medicine. **Kiel:** Dr. Julius Raacke of the Clinic for Mental Diseases has been granted the title of Professor. **Odessa:** Dr. Shchegoleff, Extraordinary Professor of Surgery, has been promoted to an Ordinary Professorship. **Vienna:** An Institute of the History of Medicine is to be established under the direction of Professor Neuburger and Professor von Töply. **Würzburg:** Dr. Adolf Treutlein has been recognised as *privat docent* of Marine and Tropical Hygiene.

DONATIONS AND BEQUESTS.—By the will of Mr. Aubrey Hillman, of Lewes, Sussex, £1000 are bequeathed to the Lewes Dispensary and Infirmary and Victoria Hospital, Lewes. The executors of the late Mr. J. L. Toole have sent to Charing Cross Hospital the sum of £900 for the purpose of endowing a bed in memory of the famous actor. The executors have also given to the National Hospital for the Paralysed and Epileptic, Bloomsbury, £225. The residue of the estate of the late Mr. William Bykur of Selwood, Dorset, which will probably amount to £20,000, will be

divided among the following institutions: Royal Free Hospital, Guy's Hospital, the London Hospital, Middlesex Hospital, the East London Hospital for Children, Shadwell, the Victoria Hospital, Bournemouth, the North London or University College Hospital, and the Westminster Hospital.

St. John's House, for many years in Norfolk-street, Strand, has removed to 12, Queen-square, Bloomsbury.

UNIVERSITY OF CAMBRIDGE.—The Third M.B. Examination, Part II, will begin on Tuesday, April 23rd, and the examination for M.C. on Thursday, April 25th. The names of the candidates have to be sent to the Registry by April 9th.—Dr. R. M. Simon has been appointed an examiner in medicine in the place of Professor W. Osler.

SELF-WILLED LEPERS.—A number of lepers some time ago, discontented with their lot, went to St. Petersburg to air their grievances, and after a time were sent back to the leper establishment of Yamburg. Now the head medical officer of the Alaphusovsk Hospital has reported the receipt of a letter from them, says the *Noroe Vremya*, stating that they have no medical man in attendance and that very soon they will again betake themselves to St. Petersburg to be cared for there; and he hopes that the requisite measures will be adopted to prevent their proposed second unsolicited visit to the capital.

THE HOSPITAL SATURDAY FUND.—At a meeting of the board of delegates held on Jan. 19th at the offices of the Fund, Gray's Inn-road, under the presidency of Sir Savile B. Crossley, it was unanimously resolved, on the recommendation of the distribution committee, that a sum of £23 89s 14d. should be awarded to the 106 participating hospitals, dispensaries, and convalescent homes as follows: 31 general hospitals, £8102 2s; 15 cottage hospitals, £312 14s; 76 special hospitals, £7938; 31 dispensaries, £911 10s; 23 convalescent homes, £1469 14s; 17 nursing institutions, £385 8s; and 13 miscellaneous (including ambulance, distribution, and surgical appliance committee), £4779 6s.

PUBLIC VACCINATORS AND POOR-LAW MEDICAL OFFICERS.—At a meeting of the Liskeard board of guardians held on Jan. 19th a discussion arose in reference to the appointment of a district medical officer. The guardians had made a stipulation with this gentleman, who was a public vaccinator as well as a district medical officer, that if he resigned one office he must resign both. The Local Government Board, however, would not sanction the appointment if these conditions were imposed as it held that the medical officer was eligible for either position as long as he resided in the district. Eventually a member gave notice that at a future meeting he would move that the appointment should be given according to the instructions of the Local Government Board.

THE ITALIAN HOSPITAL.—The annual meeting of the supporters of the Italian Hospital in Queen-square, London, W.C., was held on Jan. 18th, the Italian Ambassador, who is the president of the hospital, being in the chair. The committee's report stated that upwards of 14,000 patients, including more than 6000 British subjects, had been treated during the year. Dr. Michael Castaneda, consulting physician to the hospital and chairman of the committee, said that the King of Italy had sanctioned a scheme which had been brought forward to establish an endowment for the hospital. A subsequent speaker complained of the heavy local rates which absorbed between £250 and £300 a year. It was stated that the Italian Government made an annual grant of £100 and that £500 had been received from King Edward's Hospital Fund for London. The members of the committee were re-elected and the proceedings terminated with the usual votes of thanks.

LITERARY INTELLIGENCE.—The Liverpool School of Tropical Medicine is issuing a new periodical entitled "The Annals of Tropical Medicine and Hygiene," which bids fair to be of great value to the medical profession. The first number of the Annals will appear early in 1907 and will replace the series of separate memoirs of the Liverpool School of Tropical Medicine, several of which have been published. Many of these memoirs have been noticed in our columns as they appeared, and if the standard of their excellent printing and profuse illustration is maintained in the new Annals we think that the

KING EDWARD VII. SANATORIUM, Midhurst, Sussex.—Junior Assistant Medical Officer, unmarried. Salary £100 per annum, with board, lodging, and attendance.

LIVERPOOL HOSPITAL FOR CONSUMPTION.—Honorary Assistant Physician.

LONDON LOCK HOSPITAL.—Surgeon to Out-patients.

MANCHESTER, ANCOATS HOSPITAL.—Resident House Physician. Salary £20 per annum, with board, &c.

MANCHESTER, MOSCOPPE FEVER HOSPITAL.—Fourth Medical Assistant. Salary £100 per annum, with board, lodgings, and washing.

MANCHESTER, ST. MARY'S HOSPITALS FOR WOMEN AND CHILDREN.—House Surgeon for six months. Salary £25, with board and residence.

NEWCASTLE UPON TYNE, CITY HOSPITAL FOR INFECTIOUS DISEASES.—Resident Medical Assistant. Salary £104 per annum, with board, lodging, &c.

NEWCASTLE UPON TYNE AND NORTHUMBERLAND SANATORIUM FOR CONSUMPTION, Barrasford-on-Tyne.—Resident Medical Officer. Salary £150 per annum, rising to £220, with board and laundry.

PADDINGTON GREEN CHILDREN'S HOSPITAL, London, W.—Honorary Anaesthetist.

PLYMOUTH, SOUTH DEVON AND EAST CORNWALL HOSPITAL.—Assistant House Surgeon for six months, renewable. Salary £50, with board, residence, and washing.

REETH UNION DISTRICT AND WORKHOUSE, Yorkshire.—Medical Officer. Salary £57 10s.

ROYAL EAR HOSPITAL, Dean street, Soho, W.—Two Clinical Assistants for six months.

ROYAL HOSPITAL FOR DISEASES OF THE CHEST, City road, E.C.—Resident Medical Officer for six months. Salary at rate of £120 per annum, with apartments, board, and washing.

ST. BARTHOLOMEW'S HOSPITAL.—Surgeon and Assistant Surgeon to the Throat Department.

STAFFORD, STAFFORDSHIRE GENERAL INFIRMARY.—Assistant House Surgeon for six months. Salary £31, with board, residence, and laundry.

STROUD GENERAL HOSPITAL.—House Surgeon. Salary £100 per annum, with board, lodging, and washing.

TENBORO, ISLE OF WIGHT, ROYAL NATIONAL HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST.—Assistant Resident Medical Officer, unmarried. Salary £100, with board and lodging.

VICTORIA HOSPITAL FOR CHILDREN, Tite-street, Chelsea, S.W.—Physician to the Out-patients.

WEST BROMWICH DISTRICT HOSPITAL.—Resident Assistant House Surgeon, unmarried. Salary £50 per annum, with board, residence, and washing.

WESTERN GENERAL DISPENSARY, Marylebone-road, N.W.—Honorary Surgeon.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies as Certifying Surgeon under the Factory and Workshop Act at Malton, in the county of York, and at East Linton, in the county of Haddington.

Births, Marriages, and Deaths.

BIRTHS.

BATTLE.—On Jan. 21st, at Harley-street, Cavendish-square, W., the wife of William Henry Battle, F.R.C.S., of a son.

COOKE.—On Jan. 25th, at Bridge-street, Cambridge, the wife of Arthur Cooke, F.R.C.S., of a son.

ELLIS.—On Jan. 23rd, at London-road, Leicester, the wife of L. Erasmus Ellis, M.D., of a son.

ROGERS.—On Jan. 24th, at Sutherland-avenue, W., the wife of David de Sola Cohen Rogers, L.D.S. R.C.S. Eng., of Buenos Aires, of a son.

MARRIAGE.

HEDLEY-HALLIDAY.—On Jan. 12th, at St. Mary's, Harrow, by the Rev. T. Wayland Joyce, assisted by the Rev. R. Howel Brown, vicar of Enfield, Dr. John Prescott Hedley, son of Dr. and Mrs. Hedley, Middlesbrough to Miss Kathleen Halliday, daughter of Mr. and Mrs. James Halliday, Fishers, Harrow.—At home, 11, John-street, Mayfair, W., March 12th to 17th, 1907.

DEATH.

OLDHAM.—On Jan. 24th, at Brighton, Charles James Oldham, F.R.C.S., aged 62 years.

N.B.—A fee of 1s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

COPPERED PEAS.

At the Bournemouth police court on Jan. 18th a number of local grocers were each fined 40s., including costs, for selling bottled green peas mixed with copper salt. According to the analytical reports of the borough analyst, Mr. F. A. Cripps, F.I.O., the five samples contained copper in quantities equivalent to copper sulphate in the following proportions per pound of the whole sample and of the sample exclusive of liquor: 2.04 grains and 3.35 grains; 2.5 grains and 3.9 grains; 2.02 grains and 3.05 grains; 1.85 grains and 2.8 grains; 1.59 grains and 2.45 grains. As from one-quarter to two grains is the quantity allowed by the British Pharmacopoeia as an astringent, it was stated that three or four ounces of some of the samples would contain a good astringent dose. Mr. Cripps said he had found that from 30 to 60 per cent. of the copper salt was dissolved by pepsine in two hours. In six hours 90 per cent. was dissolved, while in pepsine and pancreatine almost the whole was digested. He further gave it as his opinion that the cause of the divergence of medical opinion as to the effects of copper salts on the human system was that some of them conducted their experiments with the inorganic salts while others used the organic. Mr. P. W. G. Kunn, medical officer of health of Bournemouth, also gave evidence for the prosecution and suggested that the eating by a child of a quantity of the peas under consideration would lead to serious or even fatal consequences. Copper was a coloring "fakement" and did not add to the food value of the product. There were bottled peas on the market prepared without the addition of copper sulphate and he had eaten them himself. Sulphate of copper being a poison, its use for this purpose was risky.

Without entering into the vexed question of whether small quantities of copper salts are harmful or not, we can say in the most emphatic way that all foodstuffs containing this or any other colouring matter should be definitely labelled with an intimation of the quantity of the colouring matter per pound employed and with a statement of its nature. The argument of the traders who use these colouring matters is always the same: first, they argue that it does no harm; and secondly, that people will not buy the foodstuff unless it is coloured. This being so, it can do no harm to trade to let the customer know that he is buying, according to the trader, a harmless substance, and one which he likes. But until such labelling is made compulsory the trader will never sell goods with such a label, for he knows very well that most people would not buy peas or other foodstuffs if they were told that they contained copper salts. The Departmental Committee on Food Preservatives recommended the absolute prohibition of copper salts for "greening" vegetables.

A POINT IN ETHICS.

To the Editors of THE LANCET.

SIRS,—Will you kindly give me your opinion upon the following case? Last Friday I was called to a woman who had just had a miscarriage. I attended her for some hours and left her quite comfortable. I visited her every day and on the fourth day I found her sitting up and she told me she had been moving about from one room to another for a short time. On the sixth day I am called urgently to her and found her in pain and losing blood. I gave some ergot and on examination found nothing to account for it. There was no febrile reaction. She passed a rather bad night, but in the morning was more comfortable. On going to see her on the same evening I am told by the servant that her mistress has called in a nurse who has brought her own doctor. How should I act in those circumstances?

Jan. 25th, 1907.

I am, Sirs, yours faithfully,

MIDWICHS.

* * * If the patient wishes in future to be attended by the nurse's "own doctor" she has a right so to be attended and our correspondent should withdraw from the case. The nurse's "own doctor" would, however, be acting unprofessionally if he took over the case without previously informing our correspondent.—Ed. L.

HASTINGS AND ST. LEONARDS.

At the request of the mayor and town council of the borough of Hastings Dr. A. Scarslyn Wilson, medical officer of health of the borough, has written a small pamphlet entitled "Notes on Hastings and St. Leonards," dealing with the climatology and sanitary condition of the borough. The pamphlet is intended for the information of medical men who may be called upon by their patients for advice in the selection of a suitable health resort. It is a pity that our home health resorts do not receive a larger amount of patronage than is usually accorded to them. Certainly the climate of Hastings offers advantages to certain classes of invalids, abundance of sunshine and the relative absence of fog being two of the chief features. The pamphlet, which contains in a brief compass some very useful and interesting information, is illustrated by several reproductions of photographs of Hastings and St. Leonards.

Appointments.

Successful applicants for Vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.

BEGG, CHARLES MACKIE, M.D., M.R.O.P. Edin., has been appointed Public Vaccinator at Wellington, New Zealand.

BLUCKE, HENRY FREDERICK STOKES, L.R.O.P., M.R.C.S., has been appointed Medical Officer of Health of Shaftesbury, Dorset.

CANN, FRANCIS JOHN HUGHES, M.B. Lond., L.R.O.P., M.R.C.S.; has been appointed Honorary Medical Officer to the Dawlish Cottage Hospital.

CHEATLE, O. T., M.R.C.S., L.R.O.P. Lond., has been appointed Certifying Surgeon under the Factory and Workshop Act for the Burford District of the county of Oxford.

COPLAND, MYER, M.D. Lond. (State Medicine), D.P.H. Camb., has been appointed Demonstrator of Bacteriology in the Faculty of Medicine of the University of Leeds.

ELDER, DOUGLAS, M.B., Ch.B. Liverp., has been appointed Pathologist to the King Edward VII. Sanatorium, Midhurst, Sussex.

FENTON, W. J., M.D. Cantab., M.R.C.P. Lond., has been appointed Assistant Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

HOGG, ALEXANDER WILSON, M.B., B.S. Edin., has been appointed Public Vaccinator at Wellington, New Zealand.

HUDSON, ARTHUR, L.R.O.P., M.R.C.S., D.P.H. Camb., has been appointed Honorary Medical Officer to the Dawlish Cottage Hospital.

LAWRENCE, O. J. MONTAGU, L.S.A., has been appointed Junior House Surgeon at the Borough Hospital, Birkenhead.

LOVELY, CHARLES NEWTON, M.D., B.S. Durh., has been appointed Honorary Medical Officer to the Dawlish Cottage Hospital.

MCCORMICK, WILLIAM MILLIGAN, M.B., M.S. Glasg., has been appointed Public Vaccinator at Tokomairiro, New Zealand.

RAVES, LESLIE, M.R.C.S. Eng., L.R.O.P. Lond., has been appointed Junior Resident Medical Officer at the Royal Waterloo Hospital for Children and Women.

ROBINSON, H. BETHAM, M.S. Lond., F.R.C.S., has been appointed Surgeon to St. Thomas's Hospital.

SAWARD, A. H. M., M.R.C.S., L.R.O.P. Lond., has been appointed Certifying Surgeon under the Factory and Workshop Act for the Richmond District of the county of Surrey.

STEVENS, WILLIAM MITCHELL, M.D. Lond., M.R.O.P. Lond., M.R.C.S., has been appointed Honorary Consulting Physician to the Royal Hamadryad Seamen's Hospital, Cardiff.

STUART, HACKWORTH, M.D. Lond., F.R.C.S. Eng., D.P.H. Cantab., has been appointed Medical Officer to the Staffordshire County Industrial School, Werrington, Stoke-on-Trent.

THIPP, CHARLES LLEWELLYN HOWARD, M.R.C.S., L.R.O.P., L.S.A., has been appointed Honorary Medical Officer to the Dawlish Cottage Hospital.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement (see Index).

BATH ROYAL UNITED HOSPITAL.—Resident Medical Officer. Salary £100 per annum, with board, lodging, and washing.

BIRMINGHAM, QUEEN'S HOSPITAL.—Honorary Physician.

BRECON AND RADNOR JOINT COUNTY'S ASYLUM, Talgarth, R.S.O., Breconshire.—Assistant Medical Officer, unmarried. Salary £140 rising to £170 per annum, with apartments, board, washing, and attendance.

BRISTOL EYE HOSPITAL.—House Surgeon. Salary £80, with board and residence.

CENTRAL LONDON THROAT AND EAR HOSPITAL, Gray's Inn-road.—Registrar for In patients. Salary 20 guineas a year.

CHELSEA, BROMPTON, AND BELGRAVE DISPENSARY, Manor street, King's-road, Chelsea.—Visiting Medical Officer.

DUMFRIES AND GALLOWAY ROYAL INFIRMARY.—Assistant House Surgeon. Salary £25 per annum, with board and washing.

GLASGOW DISTRICT ASYLUM, Gartloch.—Resident Assistant Medical Officer. Salary £125, with board and lodging.

GLOUCESTER GENERAL INFIRMARY AND GLOUCESTERSHIRE EYE INSTITUTION.—Surgeon.

HAMPSHIRE GENERAL HOSPITAL.—Resident Medical Officer. Salary £20 per annum, with board and residence.

HASTINGS, ST. LEONARDS, AND EAST SUSSEX HOSPITAL.—Assistant House Surgeon for six months. Honorarium £20, with residence, board, and washing.

TUESDAY (5th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chancery-street, W.C.).—4 P.M.: Dr. J. W. Carr: Clinique. (Medical.) 5.15 P.M.: Lecture.—Mr. E. T. Collins: Physiological Appearances of the Fundus Oculi.

POST-GRADUATE COLLEGE (West London Hospital, Hammer-smith-road, W.).—10 A.M.: Dr. Moullin: Gynaecological. 2 P.M.: Medical and Surgical Clinics. Dr. Ball: Diseases of the Throat, Nose, and Ear. 2.30 P.M.: Operations. Skiagraphy. Dr. Abraham: Diseases of the Skin. 5 P.M.: Clinical Lecture.—Mr. Dunn.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—10.30 A.M.: Clinique.—Medical Out-patient (Dr. Auld). 2.30 P.M.: Surgical Operations (Mr. Carson). Cliniques: Gynaecological Out-patient (Dr. Gilles). Surgical Out-patient (Mr. Edmunds).

Morris: Diseases of the Skin. Out-patient Demonstrations.—10 A.M.: Surgical and Medical. 12 noon: Skin. 3.15 P.M.: Special Lecture.—Mr. Carless: Some Injuries about the Elbow.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC (Queens-square, Bloomsbury, W.C.).—3.30 P.M.: Clinical Lecture.—Dr. J. Taylor: Epilepsy.

CHARING CROSS HOSPITAL.—4 P.M.: Demonstration.—Dr. I. Bruce: (Electrical). (Post-Graduate Course.)

WEDNESDAY (6th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chancery-street, W.C.).—4 P.M.: Dr. J. Pardee: Clinique. (Surgical.) 5.15 P.M.: Lecture.—Dr. E. Cautley: Constipation in Infancy and Childhood.

POST-GRADUATE COLLEGE (West London Hospital, Hammer-smith-road, W.).—10 A.M.: Dr. Ball: Diseases of the Throat, Nose, and Ear. Dr. Saunders: Diseases of Children. 2 P.M.: Medical and Surgical Clinics. 2.30 P.M.: Operations. Skiagraphy. 5 P.M.: Dr. Bedard: Practical Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—2.30 P.M.: Cliniques.—Dermatological (Dr. Meachen). Ophthalmological (Mr. Brooks). Medical Out-patient (Dr. Whipple). 4.30 P.M.: Lecture.—Mr. R. P. Brooks: Ocular Headaches.

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 P.M.: Operations. 2.30 P.M.: Dr. R. Wells: Medicine. 3.30 P.M.: Mr. Cargill: Ophthalmology. Out-patient Demonstrations.—10 A.M.: Surgical and Medical. 11 A.M.: Eye.

CENTRAL LONDON THROAT AND EAR HOSPITAL (Gray's Inn-road, W.C.).—5 P.M.: Demonstration.—Dr. A. Wyllie: Pharynx.

THURSDAY (7th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chancery-street, W.C.).—4 P.M.: Mr. Hutchinson: Clinique. (Surgical.) 5.15 P.M.: Lecture.—Dr. F. J. Smith: Some New Ideas on the Old Subject of Indigestion.

POST-GRADUATE COLLEGE (West London Hospital, Hammer-smith-road, W.).—2 P.M.: Medical and Surgical Clinics. 2.30 P.M.: Operations. Skiagraphy. Mr. Dunn: Diseases of the Eye. 5 P.M.: Lecture.—Mr. Baldwin: Practical Surgery.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—2.30 P.M.: Gynaecological Operations (Dr. Gilles). Cliniques.—Medical (Dr. Whitting). Surgical Out-patient (Mr. Carson). 3 P.M.: Clinique.—Medical In-patient (Dr. Chappel).

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 P.M.: Operations. 2.30 P.M.: Dr. G. Rankin: Medicine. 3.15 P.M.: Sir W. Bennett: Surgery. 4 P.M.: Dr. H. Corper: Radiography. Out-patient Demonstrations.—10 A.M.: Surgical and Medical. 12 noon: Ear and Throat.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester-square, W.C.).—6 P.M.: Chesterfield Lecture.—Dr. M. Dockrell: Syphilis as it modifies other Eruptions of the Skin: Symptoms, Diagnosis, and Treatment.

CHARING CROSS HOSPITAL.—4 P.M.: Dr. Galloway: Demonstration (Medical). (Post-Graduate Course.)

HOSPITAL FOR SICK CHILDREN (St. Ormond-street, W.C.).—4 P.M.: Lecture.—Dr. Batten: Cerebellar Tumours.

FRIDAY (8th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chancery-street, W.C.).—4 P.M.: Dr. J. Horne: Clinique. (Throat.)

POST-GRADUATE COLLEGE (West London Hospital, Hammer-smith-road, W.).—10 A.M.: Dr. Moullin: Gynaecological. 2 P.M.: Medical and Surgical Clinics. Dr. Ball: Diseases of the Throat, Nose, and Ear. 2.30 P.M.: Operations. Skiagraphy. Dr. Abraham: Diseases of the Skin. 5 P.M.: Lecture.—Dr. Abraham: Cases of Skin Disease.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—9.30 A.M.: Clinique.—Surgical Out-patient (Mr. H. Brooks). 2.30 P.M.: Surgical Operations (Mr. Edmunds). Cliniques.—Medical Out-patient (Dr. Auld). Ophthalmological (Mr. Brooks). 3 P.M.: Clinique.—Medical In-patient (Mr. Leslie).

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 P.M.: Operations. 2.30 P.M.: Dr. R. Bradford: Medicine. 3.15 P.M.: Mr. McGavin: Surgery. Out-patient Demonstrations.—10 A.M.: Surgical and Medical. 12 noon: Skin. 2.15 P.M.: Special Lecture.—Dr. R. Bradford: Thoracic Aneurism.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC (Queens-square, Bloomsbury, W.C.).—3.30 P.M.: Clinical Lecture.—Dr. J. Taylor: Optic Nerve Changes in Nervous Diseases.

SATURDAY (9th).—POST-GRADUATE COLLEGE (West London Hospital, Hammer-smith-road, W.).—10 A.M.: Dr. Ball: Diseases of the Throat, Nose and Ear. 2 P.M.: Medical and Surgical Clinics. 2.30 P.M.: Operations. Skiagraphy.

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 P.M.: Operations. Out-patient Demonstrations.—10 A.M.: Surgical and Medical. 11 A.M.: Eye.

During the week marked copies of the following newspapers have been received: Scarborough Evening News, Bedford Standard, Cornish Times, Westminster Gazette, Liverpool Post, Manchester Guardian, St. Andrews Sentinel, Dublin Telegraph, Manchester Dispatch, Brighton Evening Argus, Manchester Weekly Times, Medical Gazette, Leeds Mercury, &c.

EDITORIAL NOTICES.

It is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office.

Lectures, original articles, and reports should be written on one side of the paper only, AND WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WRITTEN ON THE BLOCKS TO FACILITATE IDENTIFICATION.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale and advertising departments of THE LANCET should be addressed "To the Manager."

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

THE INDEX TO THE LANCET.

The Index and Title-page to Vol. II. of 1906, which was completed with the issue of Dec. 29th, were given in THE LANCET of Jan. 5th, 1907.

VOLUMES AND CASES.

VOLUMES for the second half of the year 1906 are now ready. Bound in cloth, gilt lettered, price 18s., carriage extra.

Cases for binding the half year's numbers are also ready. Cloth, gilt lettered, price 2s., by post 2s. 3d.

To be obtained on application to the Manager, accompanied by remittance.

TO SUBSCRIBERS.

Will Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newsgents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and not to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will insure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

The rates of subscriptions, post free, either from THE LANCET Offices or from Agents, are:—

FOR THE UNITED KINGDOM.				TO THE COLONIES AND ABROAD.			
One Year	...	...	£1 12 6	One Year	...	...	£1 14 8
Six Months	...	...	0 16 3	Six Months	...	...	0 17 4

An Address

03

THE TRUE AIM OF MEDICAL EDUCATION
AND THE EVIL OF THE EXAMINATION FETTER.*Delivered before the Hunterian Society on Feb. 15th, 1907.*By LAURISTON E. SHAW, M.D. LOND.,
F.R.C.P. LOND.,PHYSICIAN TO GUY'S HOSPITAL AND MEMBER OF THE SENATE OF
THE UNIVERSITY OF LONDON.

GENTLEMEN,—The subject matter of the annual orations given before the Fellows of the Hunterian Society has not been quite so varied as might have been expected if every Fellow invited by the Council to undertake the duty had been given as free a choice of theme as was kindly allowed to me on the present occasion. Possibly in the earlier days of its institution the authorities expressed a wish that the address should deal definitely with the life and work of the great man whom now as then it is our delight to honour. Even without any such hint the entrancing interest of John Hunter's personality may have led my predecessors in this office to turn again and again to the pleasing task of laying before their fellow practitioners the stimulating example of this great researcher's life-long labours. Every medical man who studies the history of Hunter's life will be encouraged to do what lies within his power to forward the science and art of his profession. Need I then apologise for bringing before you the subject of medical education which in its broadest sense lies at the root of all medical progress? Education rightly carried out may enable every future medical practitioner to follow to some extent, however humbly, in Hunter's footsteps, but unintelligently pursued may so deaden the germ of observation with which all of us are born that none but a genius of the first rank will be able to rise above the dull level of average authority.

The records of the first years and the last hours of John Hunter's life afford material for thought to those interested in medical education. The absence of any formal instruction in school work such as at the present day constitutes what is called preliminary education has not escaped the notice of his numerous biographers. At the age of 21 years, when John Hunter commenced his study of medicine in his brother's dissecting room, it is certain he could not have passed the simplest preliminary examination in arts that has ever been imposed by any diploma granting body upon its intending students. No one, perhaps, would say that this absence of ordinary routine school education was the cause of Hunter's later extraordinary mental development. It is, however, an open question whether a firm disciplinary control by schoolmaster and university tutor over Hunter's earlier years might not have so curtailed his inquisitive and reflective faculties as to have changed one of our most brilliant thinkers into a merely successful practitioner. The failure of the schoolmaster to exercise control over budding genius is an outstanding feature in the biographies of many great men. The relation between this early refusal to be guided by masters and the subsequent power to lead mankind is worthy of careful study. Geniuses are too rare and too eccentric to allow us lightly to draw deductions as to the proper methods of their cultivation. This common feature in the early history of many brilliant men should, however, give pause to our efforts to force into a common mould every expanding brain for whose development we may be responsible.

Turning to the tragic circumstances of Hunter's painful and sudden death may we not speculate that the evening of our great man's life was sacrificed to his own appreciation of the evils of traditional bondage in educational matters? The excitement which caused his fatal heart failure at the age of 65 years was due to his vigorous protest before his colleagues at St. George's Hospital against the exclusion from the advantages of his teaching of men whose preliminary instruction fell short of official requirements. No doubt Hunter recognised that if the same barriers had been set up in his own case he would have been shut out from the

in which he could not but know that he had attained remarkable success.

While these incidents at either end of Hunter's life raise interesting questions as to the need and value of systematic education a perusal of his writings directs the reader's attention to the effect of its absence upon his own literary style. Professor T. Clifford Allbutt, whose keen criticism of his medical brethren's English hangs over all of us like a nightmare, can only forgive Hunter's defective powers of expression because of the genius of the man. "John Hunter," he says, "an illiterate genius clutching inarticulately at the evasive shadows of truth commands our labour and our time." The two-fold power so seldom owned by one man of searching out the hidden facts of nature and of telling in clear language the truths that he has learnt will always command our highest admiration. The graceful literary style which lures us on to read the immature reflections of the untrustworthy observer is one of the most dangerous possessions. Might not a facile pen have too early drawn John Hunter from his bench to his writing table? If he could have told us more fluently what he saw would he have seen so much?

These aspects of Hunter's life and work serve to remind us of the great power for good or evil which the method of his education may have upon each individual of the medical profession. The society founded to commemorate Hunter's work seems a very proper body to consider how far this power is sufficiently taken into account at the present day. I submit the subject of this address to my fellow Fellows of this society confident of their interest in the matter and of their power to influence public opinion if they are convinced of the necessity of change. Improvements and modifications of methods of education are seldom welcomed by those actively engaged in carrying out existing schemes. If we would reform our universities we must not appeal exclusively to the Dons; nor can we rely on the initiative of the headmasters to remove defects from our great secondary schools. It is from the general public, and especially from the parents of intending scholars, that the motive power for general educational reform must come. In any movement for applying modern educational principles to the course of study for medical practitioners the Fellows of such a society as our own, showing by their fellowship their interest in the progress of medical knowledge and unfettered by the traditions that bind too many of our teachers, may surely be trusted to take an active part.

You will, I think, be glad to hear that it is to general principles rather than to details that I propose to ask your attention. I do not propose to enter into the vexed question of the length of the different stages of the curriculum nor of the actual subjects appropriate to each stage. On the much-debated point of the subjects of the preliminary education demanded before admission to technical instruction I will only say this. In my opinion the profession would be well advised to refrain from adding to the existing difficulties of the schoolmaster by requiring an intending medical student to specialise in any way during his school days. We want to give the best brains of the best boys from the best schools the opportunity of being devoted to medicine and we can well take the risk as to the particular material stored within those brains being of the sort we should expect *a priori* to be most useful.

The point to which I would particularly ask your attention is the blighting influence of the examination system upon the whole work of teachers and pupils from beginning to end of the modern medical curriculum. I desire to maintain the thesis that the examination fetter, if I may so call it, is year by year gaining a greater hold on medical education; that its influence is wholly detrimental to our true aims and has a demoralising effect upon both the parties engaged in teaching; and, moreover, that this is the case, notwithstanding the fact that the peculiar features of medical education make it easier than in almost any other branch of study to free ourselves from the trammels of the system if those interested could be brought to appreciate the evils of the present position. The task of gaining a general agreement upon the failure of present methods to secure our highest aims, though difficult, should not discourage us. The harmful influence of examinations upon learning has long been clearly recognised by educational experts and is daily gaining more general acceptance. In many departments of

Never can teacher or pupil forget the examiner's existence. Each is handicapped at every step by the question, Will this work pay? At the end of this hour's study shall I be a better answering machine? I have taught in a medical school for over 20 years and I know, alas, only too well, the sort of teaching that will "pay" in this sense. In a desperate desire to get my pupils through their examinations so that they could begin to work for work's sake, the only sort of work that's worth doing, I have deliberately crammed them. Often my conscience has revolted against it, and I have taken advantage of their faith in my powers to get them through their examinations by engaging them in work that would improve the powers of their minds. After a time my subterfuge would be found out. As I adopted one or other of these methods, the method of cramming or of attempted mental development, I could fill or almost empty my out-patient room with certainty. For with the best intentions none but the highest class of student can afford to seek true learning until he is through his examinations. Too often when this time comes the student is obliged to separate himself from his hospital, and if he still has a desire for learning he is handicapped by the isolation of private practice. But in many cases, whether thus handicapped or more fortunately placed, the student finds that his crammed brain is no longer capable of rational development. His desire for knowledge, his powers of observation, his capacity for reflection, his judgment, and his reasoning faculties have all been crushed, some perhaps out of existence, by the 15 or 20 years of systematic education that he has suffered under the domination of the examination fetich.

Some will no doubt regard this picture as over-coloured. They will recall their own experience as candidates at examinations and will fail to recognise such disastrous results as I have here portrayed. While the act of preparing for an external examination, as an alternative to some better educational occupation, must in all cases be detrimental, the evil effect is less, the less are the time and labour thereby entailed. Fortunately, so long as the examination is only a pass examination and has therefore to be adapted to the requirements of men of average ability, it does but little active harm to the man whose ability is well above the average. Educational policy is generally decided by men whose ability is such that they suffered but little from a system which may have done great harm to their inferior competitors. Even men whose brilliant genius has enabled them to secure the highest competitive prizes without material harm are sometimes inclined to regard their subsequent success as being a result of, rather than in spite of, their misdirected efforts. The withdrawal at the older universities and elsewhere of the system of placing candidates in order of merit, which culminated a few days ago in the abolition of the Senior Wrangler at Cambridge, is a recognition that the struggle to secure high places in such contests is bad for the brains of those that compete and does not further the true aim of education. It is true that many Senior Wranglers have done good work in the world and many useful medical practitioners are turned out despite our present system. Cambridge believes that in future the man who would under existing conditions have been Senior Wrangler will be a better man because he will be deprived of the opportunity of developing his mind on wrong lines. Those who desire to see the examination system altered in medicine believe that all those men who turn out well now might turn out better, and many who turn out badly now might turn out well.

Is there any profession in which the highest mental faculties are more necessary for even its humblest members than in that of medicine? What is the use of developing only the power of a man's mind to contain facts who is destined to practise in our profession? In such a progressive science the fact of to-day is the antiquated superstition of to-morrow. What we must aim at turning out of our schools is not the man primed with a complete knowledge of all possible beliefs held by his various examiners at the date of his qualification, but a man capable of criticising these beliefs with sound judgment even if he has never heard of them before. We must turn out men sufficiently shattering of these beliefs by its progress and able to estimate the value of others introduced to take their places. Every medical man should be capable of such accurate observation and true deduction that he may, however humble his practice, be able to make distinct contributions to the advancement of learning. Nothing has been more

depressing in recent years than the progress of the idea that a special race of researchers must be bred to advance medical knowledge. Men who are to be freed from the routine of education or practice, safely shut away in their laboratories from students and patients, and prepared for their incarceration by a period of special study, preferably in Germany. In a recent controversy in the *Times* the development of such a class of researchers in neurology is advocated as the first essential step in dealing with the growth of insanity. Surely the first step is so to educate our medical officers of asylums as to make them capable of research and then to arrange their routine duties so as to allow them leisure to undertake it.

To encourage men's power of research or, as I should prefer to call it, the power of learning from everyday facts, must be our constant aim. This power exists in every sane human being at birth and it is the chief condemnation of most modern education that it tends to strangle instead of to cultivate it. If we could stop the strangling process so far as medical education is concerned and turn out all our students able to learn from what they see the result on the progress of medical knowledge would indeed be satisfactory. But apart from enabling him to take his share in the general advancement of science every private practitioner needs for his personal service to the individual patient a high development of his powers of observation and deduction. For the diagnosis of any case no amount of mere fact knowledge will avail the man who has not trained his eyes, ears, and fingers, as well as his brains, in a way not demanded in the pursuit of examinal success. This fact is indicated by the common observation at the hospitals that the best man at examinations often turns out the worst in the house appointments.

It is the fashion to upbraid our manufacturers for not finding places for university men in their works, as the wiser manufacturers on the continent and in America are said to do. How can we expect it to be otherwise when university education in England, dominated by the examination system, has such an influence even on medical students, that eminent surgeons, themselves examiners, have openly expressed the wish that they may never have a gold medalist in surgery appointed as their house officer. I have heard it stated, but can hardly believe it to be true, that in some medical schools the resident staff are selected by competitive examination. It is certainly an exception to find in any educational establishment, however successful in preparing students for examination, this system being used to select persons to carry on work within its own walls. Can we imagine a school in which the prefects or assistant masters were chosen in this way, or a university setting up a competitive examination to choose its professors? If we recognise that our house officers working under the control of their former teachers must have their powers of observation and sound judgment unimpaired, what shall we say of those who, immediately after their qualification, start forth into private practice? They do, indeed, require to maintain a judicial attitude of mind amidst the constant conflicts of rival methods of new treatments that will be submitted for their judgment. Is not the rich harvest of the synthetic chemist with his daily output of new hypnotics, nerve tonics, and cures for gout, are not the sudden rise and fall of so many methods of cure, whether by drugs, surgery, heat, light, or electricity, evidence of the need of greater development in medical students of those parts of the brain which preside over sober judgment and common sense. The ability to judge whether a new method of treatment is likely to be of value and of putting such method to a scientific test is not gained by learning by heart all the various means of treatment of every disease mentioned in the most complete system of medicine. A man who has in conjunction with his teacher properly established or failed to establish the efficacy of any single mode of treatment in a large series of cases has a sure basis on which he can safely found further experience.

One of the worst features of examinations is the tendency they have to be so conducted as to require the knowledge of an increasing number of facts from succeeding batches of victims. This raising of the standard, as it is called, is the only defence of the examiner against the crammer. Leave the number of facts required stationary and the percentage of successful candidates would steadily increase. By a careful study of examination papers and of the ways of particular examiners a teacher gradually learns to pack his pupils' brains with facts, with so much regard to the ease

education the fact that examinations still hold a prominent place is not due to any lack of hatred of their results but to the difficulty of finding an alternative. Amongst the official teachers of medicine, however, it does not appear that these evils are so widely recognised as by other bodies of teachers. This is the more to be regretted because, as I have just said, it is possible in medicine to set up without great difficulty alternative methods of securing what are supposed to be the objects of examinations.

To make my point clear I must first ask you to consider what is the true aim of medical education. It cannot, I think, be better or more briefly defined than by Matthew Arnold's statement of the true aim of education generally. "Its true aim," he said, "is to develop the powers of our mind and to give us access to vital knowledge." If this is the true aim we must consider how far the ideal modern examination is able to discover at the various stages of a man's curriculum whether his education has been carried out so as to secure this aim. The ideal examination of those who worship this fetich wholeheartedly is one conducted by an examiner who knows each candidate only as a number, or if, owing to the examination being a viva voce one, he must be brought into actual contact with a candidate shall not have seen him before, or at least shall have no previous knowledge of the "powers of his mind." It is an essential article of the true faith that an examiner of a candidate shall not have been his teacher. The only person who is really in a position to say whether the powers of the candidate's mind have actually been developed by the preceding course of study is ruled out of court when the result of that course of study is under scrutiny. What as a matter of fact can be tested by the ideally fair external examination? By an external examination I should perhaps explain is understood one in which the teacher has no part, it being usual to style an examination partly or wholly conducted by the candidate's teacher an internal examination. Only to the smallest extent can the powers of the mind at the moment be tested. One power of the mind can, perhaps, be tested by this means—the power which is commonly spoken of by teachers who are constantly engaged in a contest with external examiners as the knack of passing examinations—the ability to keep one's store of facts on the surface and to pour them out speedily in the presence of a stranger—the power which is essentially created and promoted by the crammer, a mixture indeed of memory and cheek. This knack is truly an attribute of mind, just as bulk is an attribute of muscle. It is just as illogical, however, continually to worry a man who is trying to develop the higher faculties of his mind with investigations as to his memory as it would be periodically to test the lifting power of a man who is learning to play the fiddle. The comparison between these two absurd processes is very real, for the sort of work that would increase the violinist's muscular force would actually lessen the subtle power of coördination essential to his art. In like manner does the cramming of a student's memory exercise a deteriorating effect upon his higher intellectual faculties.

How, then, is it to be explained that notwithstanding the growing appreciation of the limited power of the examination we in England came during the last half of the nineteenth century to make such extended use of it? The explanation is to be found in the fact that all Britons love fair play and a substantial majority hate patronage. They love fair play and they hate patronage much more than they believe in education. The apotheosis of the external examination took place at the time when the democracy growing in power decided that patronage could no longer be tolerated as the means of choosing candidates for positions of responsibility. The absolutely fair competitive examination first acquired its popularity, not as the final act in a course of education but as a preliminary step before conferring positions of honour or remuneration upon successful candidates. It came into general use to lessen the moral harm of nepotism which, hurtful as it was in an aristocratic and feudal community, became much more pernicious with the growth of commercialism and plutocracy. I cannot better illustrate the moral evils which the competitive examination system was intended to root out of our public services than by drawing attention to the hatred of the system by those interested in corruption. In a recently published American skit on municipal methods in that country there is a chapter on the Curse of Civil Service Reform. Mr. George Washington Plunkitt, chairman of the elections committee of Tammany Hall, is there reported as saying:

"When parties can't get offices they'll bust. They ain't far from busting point now with all this Civil Service business keeping most of the good things from them. How are you going to keep up patriotism if this thing goes on? You can't do it. Let me tell you patriotism has been dying out fast for the last 20 years. Before then when a party won its workers got everything there was in sight. That was somethin' to make a man patriotic. Now when a party wins and its men come forward the answer is, Nothin' doin', unless you can answer a list of questions about Egyptian mummies, and how many years it will take a bird to wear out a mass of iron as big as the earth by steppin' on it once in a century."

Even as a means of selecting suitable candidates the examination is coming to be recognised by others besides the bosses of Tammany Hall as very unsatisfactory. It may avoid moral harm to those engaged in selection by older methods and may insure absolute fairplay as between the candidates, but it constantly fails to secure the man best fitted for the vacant post. By no system of mere examination yet devised can the crammer and the special examination brain be got rid of. In India perhaps more than anywhere else in the British Empire has it been shown that the gift of passing examinations may often be the only valuable gift possessed by the candidate. Those who are most grateful to the examination system for the part it has played in freeing us from patronage must admit that as an instrument of selection it leaves much to be desired.

As an instrument of education the external examination became most widely used when the support of elementary schools out of public funds made it necessary to ensure that the education therein carried on deserved the approval and reward of the authorities. Here again we missed the true aim of education in the pursuit of absolute fairness. To decide in any school whether the powers of the children's minds are being developed it is necessary to rely on the word of the teacher and upon more or less imponderable impressions of the inspector. Herein lie risks of favouritism and inequality of rewards. By the external examination thousands of children can at the same moment answer the same question and examiners having no knowledge of who the candidates are or where they come from can with perfect fairness give the proper mark for every gradation of accuracy. Thus there can be distributed throughout the schools the fitting grant due to each for having taught its pupils the knack of answering questions. Fortunately, the folly of this system has now for some years been recognised so far as those children are concerned for whom the Board of Education is responsible. Something very similar, however, still obtains in the preparation of the children of the wealthy for their public school and university entrance scholarships.

In medical education, especially in London, we are to-day, except for the fact that there is no direct money payment from the State, in almost an identical condition to that of the elementary schools during the prevalence of the "payment by result" system. The teaching in our hospitals is being constantly interrupted by tests conducted by external examiners. For many of our students who are of average ability and do not fail to pass any examination such interruptions may occur as many as 12 times in the course of six years. And these interruptions are permitted to a series of courses of study which without them present almost an ideal opportunity for improving the powers of the pupil's minds. In almost every department of medical study and with proper organisation, it should be so in every department, the chief teacher and each of his subordinates is engaged in increasing the sum of knowledge of his special subject and in making and assisting others to make wise application of ascertained facts to actual problems before him. To associate the student as closely as possible in this double work of investigation and practice is to promote his education in the truest sense. The closest living contact between teacher and taught in mutual work is the surest way of developing the pupil's mental powers. But no sooner in the medical school do we introduce the student to his teacher than there is brought between them with chilling effect the spectre of the examiner. The absolutely fair person who with no knowledge of the candidate's work beyond a bare record of satisfactory attendance at so many lectures and so many hours' laboratory work will proceed at the end of three, six, or 12 months, as the case may be, to test just those unimportant things that can be tested by examination.

student's memory of things described by the demonstrator, and the men who passed were generally those who had not spent too much time on dissection.

What would I not give now as a teacher of clinical medicine if it could be arranged that the work which the men do at the bedside, in the post-mortem room, and in the laboratories could be given in their eyes its proper relative value as compared with the facts they are told at lectures and read in text-books? Really there should be no difficulty in providing for all the tangible results of each student's practical work, his clinical records, his charts, his bacteriological, chemical and hæmatological reports, together with duly attested microscopical slides, heart and pulse tracings, photographs, and drawings to be kept available for surprise visits of the inspector who should satisfy himself that the work is being properly done as well as fairly marked. How much more valuable would all these records be than those prepared under existing conditions, when every ward clerk knows that it pays better to learn what the appearances of optic neuritis are said to be than to "waste" time, as he would call it, in seeing and making a diagram of a particular example. A physician or surgeon surrounded by his small array of students working on these lines, instead of by his present flock hungering for examination tips, might hope to prove false the statement that advances in our science can only be secured by a special class of researchers. Our wards might once more become centres of learning in place of centres of teaching. I must not detain you by picturing the millennium in medical education which will appear when examination is replaced by intelligent inspection. I should run the risk of being accused of overstating my case, but not, I believe, by those who have studied the principles of education.

Already inspection has entirely replaced examination in some branches of scientific studies carried on under the control of the Board of Education. In other branches of study, particularly in Engineering, the records of work done during the instruction course are allowed to count materially towards the marks for the qualifying examination. Even in medicine a pious opinion has been officially expressed in favour of the principle of registration and inspection. The Faculty of Medicine of the University of London has recently reported as follows to the Senate:—

The Faculty is of opinion that a great educational advantage would be secured if the University were to extend its inspection to all practical work done by its undergraduates in each school with the object of allowing the report of its inspectors to carry some weight in the examinations for which the students are preparing. Though conscious of many difficulties the Faculty believes that such a scheme is possible and would urge the Senate and governing bodies of the schools to prepare for it.

Many difficulties are recognised in securing this limited use of inspection in conjunction with examination. But they will assuredly be overcome, and once the system obtains a footing it can hardly be doubted that it will ultimately be generally acclaimed as a highly satisfactory means of overthrowing the evil of the examination fetish and of allowing us to attain the true aim of medical education.

LONGEVITY.—The Rev. Hugh Pritchard of Mangaffo, Anglesey, commenced his hundredth year on Feb. 25th.—Mrs. Honor Coleman of Cleve, Bristol, celebrated the anniversary of her birthday on Feb. 22nd, having attained the remarkable age of 105 years.

ST. MARK'S HOSPITAL.—Sir Richard B. Martin, treasurer of St. Mark's Hospital, presided at the seventy-first annual meeting of the governors on Feb. 14. In moving the adoption of the report he said that the committee had been compelled to sell out stock to meet pressing demands and that the sum of £1000 in new annual subscriptions is essential for the maintenance of the work at its present level. He referred to the high character of the nursing, which is so important a factor in the treatment of the distressing diseases dealt with by the hospital. Mr. F. Swinford Edwards said that the hospital gave special treatment to a special class, but though the cost of "dressings," &c., was of necessity high an examination of the details of expenditure showed that affairs were managed most economically. A notable feature of the year under review was that though cases of great gravity had been treated the patients were being passed through the hospital more rapidly than hitherto, in other words, they were being cured more quickly. The usual votes of thanks terminated the proceedings.

A Lecture

ON

FAINTS AND FAINTING.

Delivered at the National Hospital for the Paralyzed and Epileptic, Queen's-square, London, W.C., on Feb. 14th, 1907.

By SIR WILLIAM R. GOWERS, M.D. LOND.,
F.R.S.,

SENIOR PHYSICIAN TO THE HOSPITAL; CONSULTING PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

GENTLEMEN,—You are all familiar with what is called a "faint"; many of you may know what it is "to faint," perhaps by your recollection of the first severe operation you witnessed. "Cardiac syncope," we call it in medicine. Our Anglo-Saxon ancestors called it "swooning," a word less used to-day than it was not long ago. It is related to "sigh" and perhaps arose from the irregular breathing often observed. "Faint" came to us through the French from the verb we still have in "feign." "Faint" was spelt indifferently with an *a* or an *e*. The latter spelling now retains the early meaning; with an *a* the significance has been differentiated into that which concerns us to-day. So great a change a single vowel makes, that a faint, if feigned, is a feint.

Familiar as fainting is, adequately as we seem to know it, there is much in it that we do not know. Our knowledge is just enough to obscure our ignorance. The most obtrusive feature of complete cardiac syncope is the loss of consciousness which results, evidently due to the failure of the action of the heart which precedes and attends it. But consciousness is not the result of the circulation of the blood. To say this is to state an obvious truism, for the two are totally different in nature. Hence the loss of consciousness cannot be the direct consequence of its cause. Its immediate cause must be a state of the nerve elements of the brain due to the change in the circulation. We are apt to overlook this when we think of the process of fainting, but its recognition is of great importance because consciousness may be lost from other causes. Its loss is the most common feature of the epileptic seizure. Not long ago it was thought to be a constant feature; without such loss an attack was said not to be epileptic. We now know that this is altogether erroneous. Minor attacks are common in which consciousness is only blurred, and in local spasm especially it may be unimpaired. Still, it is the dominant feature in each condition and it involves a relation between them of considerable practical importance. This is the greater inasmuch as the nature of the brain state on which it depends in each is unknown. We do not know whether it is the same or different in fainting and epilepsy. The only indications we can obtain depend on the discernment of any relation between the two.

Other questions regarding cardiac syncope need consideration. How is it that the state of the brain results from cardiac failure from the diminished circulation it causes? Perhaps the first reply that would be given to the question is that the heart's failure entails a diminution in the supply of nutrition to the brain incompatible with its function. But a little consideration will throw doubt on the adequacy of this mechanism. The renewal of nutrition of the nerve elements, the supply on which their metabolic processes depend, is from the plasma about them, derived from the blood, but for the time extravascular. At any moment the amount of this must be adequate to maintain the metabolic changes and the function that depends on these for a much longer time than that during which consciousness is maintained in syncope. How incompetent this influence must be to account for the loss is evident from the features of the fatal syncope of aortic regurgitation. The sudden death in this disease, rare though it is, is clearly syncopeal. But the loss of consciousness seems almost synchronous with the cardiac failure. In this instance we cannot even conceive that it is due to the failure of nutrition.

Another mechanism, far more definite, consists in the mechanical effect of cardiac failure. The resulting diminution in the blood pressure within the cavity of the skull, not merely from the lessened arterial pulsation but from the lessened force exerted by the blood within the arteries, must

of unpacking that the success of the dullest can be almost assured. To avoid this the conductors of every well constituted examination are constantly adding to the number and variety of the facts that may be dealt with in the questions. Thus is the time that has to be given to preparing for the examination increased. It is impossible in a subject like medicine to lengthen the curriculum, which therefore becomes more and more crowded with courses of didactic teaching.

This overcrowding of the curriculum deprives our students of the opportunities of developing qualities which, in addition to those I have above mentioned, are specially needed by them in their subsequent life's work—health of soul, health of mind, and health of body. For the development of all these leisure is essential and the aggressive tendency of the examination is largely responsible for its elimination from our schools. I know there are some who seem to believe in the verbal instruction of Watts's line about Satan and idle hands. That it is true in any case is due to the defective methods of preliminary education, upon which I cannot now enter. The boy should be taught to use his leisure, which indeed the very name of school implies, and the young man should have leisure to use profitably. Leisure is one of man's most blessed possessions and that it is the duty of each to endeavour to secure his proper share thereof and use it properly is a doctrine that should be preached by the medical profession. We should set our own house in order before we can hope to be successful preachers. Certainly our schools of medicine do not set good examples whether we look to the teachers or the pupils. As a first step to reform in this direction we should see that our students have reasonable leisure—leisure to strengthen their characters by doing such social service as lies at their hands, leisure to give their minds the rest which is essential to their development, and leisure to promote their bodily health by the necessary indulgence in physical exercise. All these things they need if they are to be useful medical practitioners, all these things they run a risk of not being able to secure owing to the ever-increasing demands of the examination system.

While examinations are thus seen to be a distinct impediment to attaining the true aims of medical education the evil effect is greater in some systems of examination than in others. The evil is greater the more "external" the examination; it is less the more "internal." The external examination, it will be remembered, is the form I have described as the ideal of the true worshipper of the examination fetish. It is carried on by one who knows the candidate only as a number and who has no knowledge of the course of education he has pursued; indeed, in the extreme case the true worshipper cares not that the candidate has pursued any course of education at all. What he knows he knows and it matters not how he knows it. The internal examination, on the other hand, is conducted by the principal teacher responsible for the course of education, the result of which the examination is designed to test. In internal examinations which are part of a course of instruction at the end of which diplomas or degrees are granted an assessor or external examiner is usually associated with the internal examiner. Inasmuch as one of the worst effects of the examination system is the introduction of a foreign and disturbing element between the teacher and his pupil, in the form of the unknown and unknowing examiner, the internal is less harmful than the external examination.

Whenever the teacher is the principal examiner the relationship between him and his pupils becomes at once more intimate. Each can afford to look into the other's mind. The teacher employing the experimental instead of the didactic method of instruction can lead his pupil into the paths of learning he is himself exploring regardless of whether they will lead to conclusions acceptable to the average examiner. Provided the powers of the assessor are not too great the teacher can devote himself to the business of improving his pupil's mind without anxiety as to the number of facts and theories that are being stored up. Nevertheless, there is always a risk that both teacher and pupil may allow their work to be subordinated to the interests of the examination and may even under this system forget the truth of one of Mr. Birrell's recent *obiter dicta*: "We tell whether a man has been well educated not by what he knows but by what he can understand."

Unfortunately, in medical education the external examination is a much commoner test than the internal and those

who would minimise the worst evils of the system should endeavour wherever possible to transform external into internal examinations. It is, indeed, the necessary first step but it will not be an easy one. Its difficulty is well shown by the fact that in some educational circles the internal system is contemptuously spoken of as "branding one's own herrings." Perhaps the application of this commercial phrase to a matter of higher education in England is to be excused when one considers the economic conditions under which higher education has had to be carried on in this country. Even a professor must live and if it is recognised by critics that the unendowed professor's living wage or less depends upon the number of students he can attract to his class, it is perhaps not remarkable that he should be suspected of being capable of branding some of his unworthy pupils AI in order to attract others to put themselves into his generous hands. To a large extent the curse of the external examination is the price we pay for the public neglect of medical education. Competition between unendowed schools prevents those in authority from trusting the teachers. The proper endowment of medical education by private munificence, as in America, or by the State, as in most civilised countries on the continent of Europe, would at once remove the chief obstacle to the institution of internal examinations. But even without adequate endowment it is possible to some extent to lessen the distrust of the teachers. By voluntary co-operation between the schools the spirit of rivalry may be eliminated and the staff may be brought to believe that mutual help may be as productive of good to education as the competitive methods of modern commercialism. By a fusion of the pecuniary interests of the schools it becomes possible to allow a free hand to the competent teacher in securing the development of his pupils' minds. The more the governors of our hospitals in university towns find themselves able to transfer to the university authorities the control of the purely educational part of their great charities, the easier will it be to assure the public that the teachers may be trusted. The medical schools in connexion with our voluntary hospitals must become to outward appearance as well as in fact public educational establishments, in order that the unwarranted suspicion may be removed that medical education is a lucrative business carried on for the private gain of the members of the staff who cannot therefore be trusted to "brand their own herrings."

Fortunately, there are indications that the public is beginning to appreciate its responsibility with regard to medical education and to recognise that endowment is as essential to the efficiency of medical schools as it is to all other institutions for higher education. Reform by this means will come slowly, and it is therefore fortunate that meanwhile other measures can be adopted to lessen the incubus of examinations, whether external or internal. It is because the study of all subjects in the medical curriculum is so essentially practical that this relief is at once possible. It has long been agreed that in all subjects in which it can be carried out the best education consists in the actual performance by the student of a properly thought-out course of observations, manipulations, and experiments, including, when feasible, real original work. This, which is usually called the experimental to distinguish it from the didactic method of teaching permits of the preservation of records and results for periodic inspection. It is the method which the late Sir Michael Foster introduced with so much success into the biological school at Cambridge. I doubt if there is any subject in the medical curriculum which could not be treated in this manner, and I am sure that every subject would be the better from the educational point of view for being so treated. I need not go into details. Two subjects at either end of the curriculum will illustrate the point, biology and clinical medicine, in both of which I have had practical experience as a teacher. What would I not have given as a demonstrator of biology if I could have insisted on such a careful preparation of dissected specimens, diagrams, and drawings as would be entailed by the introduction of a system of daily marking for observations made and practical work done, accompanied by periodic inspection. How much more thorough and instructive would have been our work than that which we did in definite preparation for a single external examination at the end of the course. It is true there was what was called a practical examination, but the possible practical tests were exceedingly few and well-known beforehand, so that success really depended on the

Recovery was then by mental confusion, not lessening faintness, and at first she could not tell where she was.

CASE 3.—Another patient, regarding whom the facts could be ascertained with considerable precision, was a woman who became prone to faint in early girlhood, especially in hot, crowded places. In these she first became pale, felt faint, and gradually lost her sight, and then, if she tried to stay where she was, she lost consciousness. Usually, when sight had failed, with help she was able to walk out of the place. During the effort dim sight returned and the fresh air quickly restored her. These are the typical symptoms of cardiac syncope. Such faints continued until she was 30 years of age, when she became liable to sudden brief loss of consciousness in which she often fell and sometimes hurt herself. After these she usually slept and usually could not afterwards recall what had happened between the attack and the sleep. One occurred in a room with the door locked; the noise of her fall alarmed her friends, who knocked at the door. She got up and opened it, then she lay down and went to sleep, but afterwards remembered nothing of the incident. Such attacks were undoubtedly epileptic and after they began she ceased to be liable to the faints. She never had a convulsive seizure but the attacks continued until she came under treatment at 42 years of age, when they were arrested by bromide; she has since continued free. There were no heart disease and no family history of epilepsy, and no cause could be ascertained except the apparently disposing influence of the cardiac faints.

These cases present strong evidence of the influence of repeated cardiac syncope in disposing to epilepsy. They suggest that the state of the nerve elements that underlies the loss of consciousness in syncope may, by repeated induction, acquire a tendency to spontaneous development, which constitutes minor epilepsy. The following case presents a similar indication, slightly different in nature. Attacks of unconsciousness occurred with the suddenness of minor epilepsy, but after an excitant such as induces syncope.

CASE 4.—A married woman, aged 33 years, came under observation on account of slight hemichorea of two months duration. She had had an attack of chorea at 19 years of age, lasting for two months, and another at 33 years of age, lasting for six months. There was no heart disease. At the age of 34 years she cut her finger badly; two days later the bandage suddenly slipped off and at the sight of the cut she instantly fell unconscious, hurting her nose in the fall. She breathed heavily for ten minutes and then recovered. When she was 37 years of age she again cut her finger slightly and immediately became "dazed," became pale, and then lost consciousness for five minutes. The first of these attacks had the definite features of minor epilepsy in suddenness and character, although excited by an occasional cause of syncope. The second was due to a similar cause and resembled syncope in its less sudden onset and in the fact that pallor preceded loss of consciousness, but before the pallor there was definite disturbance of function in the brain. The features of these attacks are of obvious interest in relation to the question of identity of nature.

Whatever is the relation of the brain process in syncope and epilepsy the two are brought together in a very practical way by the frequent difficulty of distinguishing one from the other. The difficulty often exists when it should not, and in characteristic forms of either it can scarcely arise. That it is sometimes reasonable is evident from the fact that attacks that are originally syncopal seem sometimes to become epileptic. But when the diagnostic difficulty is not reasonable it may be very real. Its reality justifies a scrutiny of its causes, which is further justified by the fact that it reveals instructive features which might otherwise escape attention.

The error of regarding minor epilepsy as cardiac faints, which is the more common, is often promoted by the natural tendency to perceive the less grave. The distress that is caused by the recognition of epilepsy naturally deters from the diagnosis and causes all reasons for doubt to receive great weight. Inclination may distort the vision even of a well-balanced mind and cause a mental astigmatism, by which lines in one direction appear more distinct. Instances of this are very common. A pertinent example came to my notice recently, which conveys a special lesson in diagnosis. A patient with no relevant disease told me, as an unimportant incident, that he had recently fainted just as he had finished his dinner. He had

taken nothing doubtful or unwise. On inquiry as to the features of the faint, it seemed that just as he had finished the meal before rising from his chair, he suddenly felt extremely sleepy and knew no more until he heard the words, "Are you better now?" from a companion who, seeing he was unwell, had saved him from falling off his chair. He had been unconscious about two minutes and became drowsy in aspect. On recovering he was well almost at once. These are not the features of a cardiac faint. Such sudden, intense, brief sleepiness is not met with at the onset of syncope and is often met with in minor epilepsy; this is true also of the dusky tint, which indicates impairment of breathing, not of the heart, while the very sudden return to the normal state is also an epileptic indication. Whatever were its immediate cause and remote significance, it was certainly not a cardiac faint.

The error of regarding attacks as syncopal when their features indicate that they are independent of the heart is promoted not only by a tendency to take the milder view but also by the fact that sometimes their characters may suggest a cardiac origin. One of these is a sensation referred to the heart or its region. When it is really an epileptic aura, it seems to indicate that disturbance of the heart is the first element and that its failure causes the loss of consciousness. Such an error is the more easy because a cardiac aura is not common in epilepsy and its occurrence may even be unknown.

CASE 5.—A boy, aged 16 years, had "fainted" about a dozen times during a fortnight, nine months before he was seen, but not again until the previous week. During this he had fainted eight times, always in the day. In the first series, each faint had begun by a sudden stab at the heart, instantly followed by unconsciousness. In the later attacks the cardiac pain was also the first symptom, but was slighter and less brief and was accompanied by a sense of nausea and giddiness. After a few seconds he fell from sudden loss of consciousness. On its return, after a "minute," he struggled and had to be held down, evidently in the hysteroid state that so often follows minor epilepsy, but never occurs after cardiac syncope. Yet the case had been regarded as one of simple cardiac faints on account of the initial pain, which was really an epileptic aura. It is noteworthy that when it became more deliberate, the disturbance spread in the central relations of the vagus, causing the sense of nausea and associated giddiness, which are not uncommon but might have been thought to be evidence of a gastric cause.

Less frequently simple cardiac faints are thought to be minor epilepsy, chiefly when the patient is a member of a family in which epilepsy has occurred. Hereditarily naturally excites suspicion as to the nature of loss of consciousness.

CASE 6.—A girl, aged 18 years, whose cousin was epileptic, had suffered from loss of consciousness several times during the preceding year and the attacks were regarded as minor epilepsy. But each had occurred under conditions capable of causing cardiac syncope. Each began with pallor and a sense of faintness; in each sight failed first and then consciousness was gradually lost. There was no rigidity, and recovery, on being laid down, was by a slowly lessening sense of faintness, without any mental confusion. The opinion that they were simple cardiac faints was confirmed by complete recovery under tonics.

As the last case shows, the fact that an attack is excited by an external influence is important as confirmation of its syncopal nature, when this is also indicated by its features. Too much weight should not be placed on the fact that it is thus induced, unless the exciting influence is distinctly such as causes syncope. Even then it should be subordinate to the character of the faint. As a general rule, in the differential diagnosis of disease, symptoms must be combined and their relative weight considered. Distinctions are not always distinctive.

Epileptic attacks also are sometimes excited by an external influence, sometimes by such as might seem likely to cause syncope. A sudden noise, such as the sudden slamming-to of a door, may cause an attack of unquestionable minor epilepsy in those who are subject to it. A sudden sound is always, as we say, "startling." The "start" is a sudden movement which represents the instant motion to escape from danger, which is so familiar to us in lower creatures. Indeed, this may have led to the term "e-motion" as a designation of the class of mental processes of which the fear that excites movement out of danger is the most frequent in the animal world. The wide and instant effect

be great. It will be effective in proportion to its suddenness, as are all variations of intracranial pressure. The instance last considered, the sudden arrest of the heart's action in aortic regurgitation, must be mechanically equivalent to a "stunning" blow on the skull. In the more gentle failure of ordinary syncope the mere diminution in pressure is conceivably adequate to induce the alteration in the nerve elements on which unconsciousness depends. As I have said, we do not know its nature nor have we enough knowledge to formulate a probable conception of it. It may be thought of as a widespread retraction of cortical dendrites, interrupting their connexion with all lower centres, but it can only be as a speculation, of value only as a tentative aid to thought.

The features of ordinary syncope merit consideration. They are dominated by the failure of the heart's action. As this lessens in strength the effect is seen, especially where it has to raise the blood against the force of gravitation, in the pallor of the face, which the brain doubtless shares. We may reasonably infer this when a cause is operative which must act on face and brain alike; but we cannot assume that the brain is anæmic whenever the face becomes pale any more than we can assume that the brain becomes congested whenever the face is suffused with the blush of emotion. This by the way. In syncope we may regard the surface change as coinciding with that beneath the surface. With it there are a sense of increasing feebleness, often undue consciousness of the heart's action, some respiratory distress which may be manifested by sighing breathing, and frequently a sense of nausea. Dimness or loss of sight often precedes loss of consciousness, probably due to the lessened blood-supply to the retina. Of all structures the retina seems the most sensitive, as indeed we might expect. Sight may suffer without consciousness. A lad under some emotional excitement in a hot, crowded room, felt faint and went out into the cold night air for a few minutes. Feeling better, he returned to the room and found that he could see nothing—all seemed black. Sight gradually returned in the course of a few minutes.

It is doubtful whether true cardiac syncope ever causes absolutely sudden loss of consciousness, except when this is due to a fatal arrest of the action of the heart. It is seldom, if ever, so sudden as to cause a hurtful fall. As a rule, the deliberate onset enables the sufferer to lie down, when gravitation ceases to hinder the flow of blood to the brain and the blood pressure is restored. The slow return of strength to the pulse and of colour to the face is attended by deeper breathing and gradually consciousness returns. With it from the first there is correct perception of surroundings, never the mental confusion and wandering or erroneous action that are common after minor epilepsy. On the other hand, after the latter there may be an instant return of a normal mental state, with no transitional sense of lessening prostration that is the usual mode of recovery from syncope. Moreover, it is important to emphasise the fact that in minor epilepsy, which alone can be confounded with cardiac syncope, there is never initial pallor of the face. This follows the onset. Error on this point is common because the patient is only closely observed after some feature of the attack has drawn attention to him. Much more frequently no change in the tint of the face is to be seen either before or after a minor seizure. This is true also of the pulse. The state of the vessels of the retina does not necessarily indicate a similar condition in those of the brain, but I once chanced to have those of the retina under clear view by the direct method of observation throughout a minor attack and no change in them could be seen.

We shall see better how imperfect is our knowledge of syncope if we consider the various causes by which the failure of the heart may be brought about. One obtrusive cause is loss of blood and another, similar in nature, is the withdrawal of a large amount of blood from the general circulation by its collection in one set of vessels. You know that fainting may occur when much fluid is withdrawn from the peritoneal cavity unless the abdominal vessels are supported by external pressure. This is, no doubt, the explanation of one of the commonest causes of fainting in strong men, violent diarrhoea or a violent purging. The flux to the intestinal vessels and the copious efflux from them render the amount of blood in the general circulation inadequate. The effect of a hot room is ascribed to a similar mechanism, the dilatation of the vessels of the surface, although in this case other influences may perhaps coöperate.

In all these cases how, we may ask, is the failure of the

heart brought about? Is it produced by the diminished flow in the arteries of the heart or by the lessened quantity within the cavities being insufficient to excite the contractions? Or does the diminution in the blood-supply to the medulla oblongata excite an impulse in the pneumogastric which causes the heart to fail? The last involves two questions. Is the inhibitory influence from the cardiac centre in the medulla excited in it primarily by the change in the circulation, or is it due to the influence of this change on the cerebral hemisphere, the effect being focussed on the medulla? It may be useless to ask these questions, but few reasonable questions are wholly useless. The same questions apply to syncope from valvular disease of the heart.

Syncope is often due to a cause that can only act through the nervous system. It may be produced by a sudden intense pain, especially if felt in the abdomen or in the vicinity of the heart. The mechanism is supposed to be a direct action on the centre for the vagus, and this is rendered probable by the proved effect of such pain on the vaso-motor system. But syncope is only known to result if the pain is perceived. In man, I think, a cause of adequate pain has not been known to produce syncope if the patient was under the influence of an anæsthetic. Hence it seems doubtful whether the effect is due to a direct action on the vagal centre; the facts suggest that it is the result of a profound influence on the sensory regions of the cortex, focussed down on the cardiac centre in the medulla. The disturbance of the cortex must also be concentrated on the cardiac centre when syncope results from sudden intense emotion.

Remarkable also is the characteristic syncope that may be caused by the sight of blood. This must be purely emotional in its production. It does not seem to be caused by depleted blood, however realistic may be the painting. A special idiosyncrasy renders some persons liable to faint when certain odours are perceived, especially those of certain flowers, even such as are purely pleasant to the majority. By what mechanism the result is produced is unknown. It is difficult to conceive that the stimulation of the olfactory nerve has a direct effect on the vagus. It seems necessary for the odour to be perceived; so that here again the influence on the cerebral cortex may be necessary for the effect. There is much mystery in the part played by the cortex in connexion with reflex processes.

Since we are ignorant of the nature of the condition of the brain structures that underlies the loss of consciousness in syncope on the one hand and in epilepsy on the other, we have no means of discerning whether it is the same in each. We know only that it is spontaneous in epilepsy, coming on without any perceptible excitant, while in syncope it is induced by the failure of the circulation. The question gives special importance to any cases in which the two conditions seem to be connected, especially in which repeated syncope passes into minor epilepsy. Such a relation constitutes indirect evidence of the essential identity of the functional state in the two conditions. It is suggested by the following cases.

CASE 1.—A girl, when about seven years old, became liable to faint on any sudden start or alarm. The faints had all the characters of cardiac syncope; there were pallor, coldness, and gradual loss of consciousness. After some years such faints occurred without any sudden excitant and became more sudden in onset. When she was 17 years old one of these attacks passed into a distinct epileptic fit, with deviation of the head, general clonic spasm, and micturition during the attacks. This case may seem inconclusive, because the early attacks may have been possibly epilepsy with excitation of the fits, although this opinion is hardly consistent with the gradual development of unconsciousness, consistent with the gradual development of unconsciousness, with preceding pallor. The following case is not open to this objection.

CASE 2.—A single woman, aged 34 years, had been liable for many years (12 or more) to apparently true fainting attacks, caused by excitement, over-fatigue, or a hot room. They began with palpitation of the heart and a sense of faintness, followed by gradual loss of consciousness, which did not become complete if she was able promptly to lie down, when she always began to recover. At the age of 25 years these faints changed in character. She became unconscious more suddenly and without any exciting cause; indeed, the onset was so abrupt that she often only knew that she had had an attack by finding herself on the floor.

another way, no less than four-fifths of these patients had lost half, or more than half, of their relatives within from three to five years, so that it is easy to understand how whole families have been destroyed and so much land has fallen out of cultivation.

A similar family incidence is seen in the sporadic disease and is best illustrated by a European series of cases, in which it is easier to follow up the histories. An examination of my notes of the Calcutta European Hospital cases of the last six years shows that the most common relationships between patients actually in hospital for the disease were parent and child in six instances and brothers and sisters in seven more, nearly always children, while in no less than three of these instances more than two children of the same household were admitted, the series in one family extending over a period of five years. Moreover, just one-third of the whole series of cases had relatives actually in hospital during this period, while a good many more gave histories of other members of their families being attacked with fevers of long duration, which were pretty certainly mostly of the same nature. This family incidence clearly points to a house infection and was the basis of the successful measures which I advocated against the disease.

The histories of the rare cases in which Europeans in Assam were attacked by kala-azar throw some further light on this question, for in all the six cases, regarding whom Mr. J. Dodds Price kindly furnished me with information, the affected men were in the habit of cohabiting with native women either in the infected lines or in three instances with one woman, who was subsequently found to be infected with kala-azar, two of them subsequently dying from the disease. Two of these last cases of infection were most important, as they occurred in parts then uninfected with kala-azar, but in each case the woman had come from an infected district. Moreover, Mr. Price knows of no instance in which a European cohabited with an infected native woman who escaped kala-azar; and when we bear in mind that it is the usual custom for such women only to come to the bungalow at night and not to eat with the European, then it becomes clear that the most likely mode of infection by a parasite occurring in the peripheral circulation is through some biting insect, in which the parasite may pass its extracorporeal stage of existence. Moreover, such a source of infection may furnish a clue to that of adult Europeans with no family history to explain it in large towns such as Calcutta, as well as among soldiers in Bengal cantonments, and is also in accordance with the increasing age incidence after early adult life to be mentioned immediately. Again, the infection of one child after another in the same house may be also readily explained on the same hypothesis, and indicates the importance of isolating, at least in a separate room, any person attacked by the disease, or better is a hospital where persistent treatment and nursing can be carried out.

Age and sex incidence.—Among tea-garden coolies, who furnish the most accurate statistics, there was no difference in the incidence of the disease on the two sexes, nor did occupation affect it. Numberless instances of husband and wife being infected one after the other were met with, it being, in fact, the exception for one of them to escape: another striking instance of house infection. In the sporadic disease in Calcutta an excess of native males are admitted, much in proportion to those of other diseases. In the European hospital there were twice as many males as females above the age of 15 years, possibly partly due to the source of infection just mentioned, but in children under 15 years of age there were 23 females to 13 males, probably due to a larger proportion of the male children living away from home at schools.

The age incidence is of great importance, the most striking fact being the number of children attacked. In my report I recorded that 25.6 per cent. of my cases occurred in children under 10 years of age, while 24.4 per cent. more were between 10 and 20 years old, making 50 per cent. under the latter age. Further, in a more recent report on the sporadic disease in Sylhet, 29 per cent. were under 10 years and 30 per cent. more between 10 and 20 years, making nearly 70 per cent. under 20 years. Among natives in Calcutta only 8 per cent. were in children under 10 years, but 40 per cent. were between 10 and 20 years, three-fifths of which were boys from 10 to 15 years old, who are much more readily brought to hospital than girls or younger children. Between from 20 to 30 years of age there were 32 per cent., 16 per cent. from 30 to 40 years, and only 4 per cent. over 40

years. Among Europeans, who readily bring their children to hospital, 20 per cent. were under 10 years and 22 per cent. more between 10 and 15 years, making no less than 42 per cent. 15 years of age or under, 22 per cent. from 20 to 30 years, and 20 per cent. over 30 years, showing once more a very high rate among the unfortunate children and a decreasing one with advancing age.

Race incidence.—It has already been mentioned that epidemic kala-azar was rare in Europeans in Assam compared with natives, but is not so very uncommon in Europeans in Calcutta in the sporadic form. The class of Europeans attacked is here of great importance, for out of 87 cases, regarding whom I have a note as to how long they had been in India, I find that no less than 87.34 per cent. were born and bred in that country and only 12.66 were immigrants from Europe. Moreover, the shortest time after arriving in India that any immigrant was attacked was eight years, a second had been 13 years, and a third 19 years in the country, while the remaining eight had all been over 20 years in India and belonged to the same class as those born in Calcutta, and, like them, were living in parts of the city where their houses were surrounded by those of native inhabitants and under conditions of overcrowding and bad sanitation. In fact, almost all these unfortunate people belonged to the poorest sections of the mixed European and native population, among whom the sanitation and cleanliness of the well-to-do official and commercial European immigrant class are an impossibility, a fact of great importance in connexion with the etiology of the disease. In marked contrast with this is an observation that I have recently made to the effect that 80 per cent. of the European immigrants admitted to hospital for typhoid fever in Calcutta had been three years or less in India, for the totally different incidence of sporadic kala-azar just mentioned in this class will prove a useful point in the differentiation of the latter disease in its early remittent stage from typhoid fever, with which it has been so much confused.

SEASONAL INCIDENCE OF KALA-AZAR.

Owing to the disease lasting from a few months to several years cases are admitted to hospital at all seasons and neither in Calcutta nor Madras is there any very marked seasonal incidence, although there is some excess of admissions of Europeans in Calcutta at the end of the cold and beginning of the hot season, especially among those coming in the early stages of the fever. Of much greater importance is the question whether the fever begins at any special season, as is suggested by the fact that the extracorporeal stages of the parasite, to be described later, only developed in my cultures below a temperature of 75° F. It is very difficult to obtain accurate histories of the beginning of the disease in many cases, especially when they are seen for the first time at a much later date, but an analysis of my notes of those patients who stated that they had had fever for not more than six months in two series of cases, in the Native Medical College and European hospitals respectively, both showed a marked preponderance commencing during the cold weather or early in the hot weather on account of the frequent long incubation period. These results can be summed up by saying that in the six months from November to April there were three times as many cases in the European series and almost four times as many in the native one as in the remaining six months of the year, a sufficiently striking fact when the difficulties of getting accurate data are considered. When in Assam I tried to work out this point from the admissions to hospital for fever on tea estates and found that most of the patients suffering from typical kala-azar in the cold season had been admitted for short attacks of apparently malarial fever in the previous rainy season from June to October. On finding that the sporadic cases in Calcutta mostly began in the cold season I wrote to Mr. Price for his matured experience on the subject and he very kindly sent me histories of all his European cases, every one of which had commenced in the cold weather, while an inquiry into his then comparatively few native patients also showed that almost all of them had developed kala-azar during the cold weather and he added: "All this is very instructive and fits in exactly with your Calcutta experience."

Taking everything into consideration I think there is sufficient evidence to prove that the great majority of patients become infected in the cold season, and I am inclined to think that infection will ultimately be found to be limited to this time of the year. The importance of this fact in connexion with prophylactic measures is clear, as it

on the cortical centres renders it easy to understand that it should sometimes excite an epileptic seizure in those who are liable; indeed, we may feel surprise that the effect is so seldom met with. A sudden alarm occasionally induces a true faint, but the alarm is usually more profound than that caused by a sudden sound, and the attack comes on deliberately.

Sudden change of posture is an occasional excitant of loss of consciousness, and it may be regarded as evidence that this is syncope if the change is to the erect posture. For the moment the flow of blood to the head must be hindered, but in some cases of undoubted epilepsy it may induce an attack. I had once an opportunity of observing such an attack. Consciousness was instantly lost; the patient became rigid and would have fallen unless supported; the conjunctival and pupillary reflexes were absolutely lost. Had it been syncope the onset would have been deliberate, preceded by pallor, and there would have been no rigidity. The mechanism of an epileptic attack thus induced is an interesting problem. The facts suggest the possibility that the sudden diminution in blood pressure, trifling as it must have been, may have caused the nerve elements to pass into the condition which underlies the unconsciousness of a complete syncope. They again bring before us the question whether this may not be identical with that of epilepsy.

Stooping, lowering the head, has the opposite effect on the intracranial circulation; it tends to increase the amount of blood in the vessels, especially when combined with flexion of the neck, hindering the return by the veins, and with some effort, which is usually the object of the stoop. The fulness of the vessels thus induced seems sometimes to cause a momentary loss of consciousness, but this is not alone effective often enough to come into relation to our present subject. A more intense mechanical congestion is induced by severe paroxysms of cough, such as those of whooping-cough. They may culminate in a moment's unconsciousness, as if the sudden increase of blood pressure produced the same functional state of the nerve elements as its sudden decrease. I may mention an interesting personal observation by one of the most distinguished physicians of the last century who had an attack of whooping-cough when nearly 60 years of age. In many of the more severe paroxysms of coughing he had a moment's loss of consciousness. The impression his own sensation gave him was distinctly that this was not the effect of the mechanical congestion; it seemed to him to be due to a process of discharge spreading from that in the medulla which caused the cough.

To the case in which epileptic attacks were induced by standing up the following presents an instructive contrast:—

CASE 7.—A woman, aged 38 years, had epileptic attacks in the night, apparently of minor character but attended by micturition. They also occurred in the day and then began with a sensation of a sudden rush to the head, followed by loss of sight and then loss of consciousness. Automatic action followed the attack. One was so sudden in onset that she fell unconscious on the floor. Thus there can be no question of their epileptic nature. In her, stooping often induced a partial attack, there was a sudden rush to the head, and complete loss of sight, which gradually returned on rising, but there was not actual unconsciousness. Otherwise these attacks, induced by stooping, resembled closely those that were spontaneous. The lesson of the case is that repletion of the vessels and increased intracranial pressure excited the state of the nerve elements which constituted the epileptic seizure. The effect, moreover, bore some resemblance to partial syncope due to cardiac failure, but was more rapid in its course.

The connexion between the cases we have considered is the fact of loss of consciousness. If we realise that the state of the cerebral nerve elements on which it depends may be similar in both syncope and epilepsy, many of the facts of the cases I have referred to become more intelligible. In epilepsy the instability of the nerve elements causes them to pass, suddenly and spontaneously, into the same state as is induced more slowly by the failure of the pressure and flow of blood which result from cardiac syncope. We can then understand that such repeated induction of this state by failure of the heart may lessen their inherent stability, until the change may occur spontaneously as definite minor epilepsy. We can also understand that a change of position which lessens slightly the blood pressure may promote the

onset of an attack of epileptic unconsciousness in those who are liable to this.

My chief object is to impress on you the fact that the functional state of the brain in syncope and unconsciousness is distinct from the failure of the blood-supply that causes it, and may be nearly the same as that which occurs in epilepsy, apart from the state of the circulation. Other objects are to direct attention to the uncertainty there is as to the precise mechanism through which the heart failure is induced by its various causes, the occasional causal relation of syncope to epilepsy, the problems of their diagnosis. Perhaps the first object I have just mentioned may now seem superfluous. The definite distinctness of the cerebral process may appear self-evident and it may seem that I have laboured overmuch to make clear that which needs no demonstrating. If so, I am well content.

ABSTRACT OF

The Milroy Lectures

ON

KALA-AZAR, ITS DIFFERENTIATION AND ITS EPIDEMIOLOGY.

Delivered before the Royal College of Physicians of London

By LEONARD ROGERS, M.D. LOND.,
F.R.C.P. LOND.,

MAJOR, L.M.S.; PROFESSOR OF PATHOLOGY AT THE MEDICAL COLLEGE, CALCUTTA.

LECTURE II.¹

Delivered on Feb. 26th.

KALA-AZAR AS A DISEASE.

MR. PRESIDENT AND GENTLEMEN,—In my first lecture I dealt with kala-azar as an epidemic, tracing its origin, spread, and decline, and referred to a similar earlier outbreak in Bengal known as “Birdwan fever.” To-day I pass on to describe the disease itself, its course, complications, and terminations, and shall show you that it is not one whit less terrible when considered individually than collectively, for it literally kills by inches after most prolonged sufferings, which we are still powerless to check to any great extent. As the latter stages of the disease are much better known than the earlier ones it will be clearer if I first describe the typical advanced condition, returning to the still rarely recognised commencement of the fever.

[With regard to the general appearances in the characteristic stages of the disease kala-azar, a number of lantern slides showing groups of cases were shown and the salient points of each were described, the main features being the marked contrast between the tumid bellies due to the very great enlargement of the spleens and sometimes also of the liver, contrasting with the great wasting of the chest, face, and limbs. Brief notes were given of a group of hospital cases which illustrated the different courses that disease might take, while a village group showed the great frequency of the affection in children, just as in malarial fever, the incidence decreasing steadily in the subsequent decades. Other groups of sporadic cases, then known as “malarial cachexia,” in the Sylhet Valley, which was not invaded by the epidemic, showed the clinical identity of the two forms of the disease, which was the principal argument of the lecturer in his 1897 report in favour of the epidemic disease in the Brahmaputra Valley being but an intensified form of malarial fever. The extreme wasting in the last stages and the occasional dropsical ascitic complication produced by a peculiar form of intracellular cirrhosis of the liver were also illustrated. The lecturer then proceeded:—]

Family distribution.—Several of the cases already referred to illustrate very well the extraordinary tendency of this disease to attack a number of persons in the same family or household, but the frequency with which this is the case will be better realised from the following figures relating to 20 successive Assamese patients seen in the Nowgong Hospital. Among their near relatives no less than 123 persons had been attacked by kala-azar, only two of whom recovered from it, while but 44 had escaped the infection, or, to put it

¹ Lecture I. was published in THE LANCET of Feb. 23rd, 1907, p. 456.

early cases in which the confirmation of the diagnosis is of great importance in order to allow of continued and adequate treatment being strongly urged on the patient, so many of whom leave hospital during a temporary remission of their fever and leave off the all-important quinine until a fresh high remittent bout comes to reduce them another stage towards the grave.

COMPLICATIONS OF KALA-AZAR.

The frequency with which kala-azar is terminated by some inflammatory complication may best be illustrated by the data from 49 necropsies made by me at the Medical College Hospital. All but seven of them showed some serious local disease, and some of them more than one. In 11 pneumonia, in ten dysentery, in seven carcinoma oris, in two each pneumococcus meningitis, purpura, cerebral hemorrhage, and pulmonary phthisis respectively, and in one pericarditis were found, while in several carcinoma oris cases staphylococci or streptococci were cultivated from the spleen, revealing a general septic infection. The extreme reduction in the polymuclear leucocytes in this disease, in which they not rarely fall to one-twentieth or less of the normal numbers, easily explains the frequency with which these patients fall victims to the specific organisms of pneumonia, dysentery, pulmonary phthisis, or the cocci of carcinoma oris in which I have never been able to find the diphtheria bacillus, which has been met with in European cases of this disease.

Hæmorrhages deserve special mention among the complications, reduced coagulability having been found by me in some of these cases, while bleeding from sloughing ulcers or from the stomach or bowel has also been seen, in addition to several cases of bleeding into the brain or its membranes.

THE TREATMENT OF KALA-AZAR.

Although much has been done to elucidate the pathology of kala-azar during the last four years, unfortunately the treatment of the disease has made no corresponding progress and is still in a most unsatisfactory state. In Madras, indeed, I am informed that almost every case is believed to die, the mortality being estimated at 93 per cent., the highest figure reached in the Nowgong tea estates by the epidemic form, while that of several hundred cases treated by Mr. Price at the height of the epidemic gave an average mortality of 85 per cent. Mr. Price's cases were treated with thymol first to exclude amylotomiasis, and quinine in moderate doses being generally used during the several periods the patients were in hospital, for it was the common opinion that quinine failed to check the fever in the same way that it did malaria, and many thought it quite valueless and used it very little, as is also the case in Madras at the present time. In my report I strongly dissented from this view and urged that quinine did have a definite effect in controlling the severity of the fever, even when it did not stop altogether, and recommended that it should be given in large doses and persisted with for months together if necessary. Further experience in Calcutta has only served to confirm me in that opinion, for I have repeatedly seen a high remittent fever reduced to a comparatively harmless low intermittent one by increasing the quantity of quinine given, 60 and in some cases 90 grains a day having been taken for considerable periods with nothing but good effects beyond being sometimes distressing to the patients. Once the temperature has fallen to the low intermittent type it can often be kept down to that point for a long time by smaller doses, one of 20 grains in the morning being commonly effectual. That this line of treatment has given far better results than those admitted by unbelievers in it will be clear from the fact that after the publication of my report Mr. Price systematically tried persevering quinine treatment, and when he wrote out for me the results of several years' experience he found that the mortality of 500 consecutive cases was but 10 per cent., the remaining 25 per cent. having permanently recovered against 4 per cent. in the earlier series quoted above. Now as these patients were indentured coolies, who remained working on the gardens, often for years, after getting over a typical attack of kala-azar (the diagnosis of which in its characteristic stages presents no difficulties at the present time to Mr. Price with his 15 years' daily experience of the disease, while in some of them the parasite was also found by spleen puncture), there can be absolutely no doubt about their permanent recovery, some of them having also been seen by me both during and after their attacks.

Moreover, these unquestionable results of Mr. Price are confirmed by my smaller experience in Calcutta under less

favourable conditions for following up my patients. Thus, out of 65 cases in the European Hospital, during the last three years of which I have notes, 18 who left the hospital in a doubtful condition I have not been able to get further news of, leaving 47 cases. Of these 47 cases 21 died either in hospital or after leaving it, 9 more who left in a worse condition than they came may be counted as having died, leaving 7, or 14·83, who left hospital after having lost their fever and greatly improved, a fair proportion of them probably recovering, and 10, or 21·27 per cent., have completely recovered and are known to have been well for from several months to upwards of a year after leaving hospital. It should be mentioned that three of the patients who recovered had also been treated with injections of staphylococcus vaccine, which appeared to have some good effect.

These figures are in close accordance with those of Mr. Price and contrast most favourably with the nearly invariably fatal results admitted by those who still deny their patients the benefit of persistent quinine treatment, although without any efficient remedy of their own, and I venture to think that in view of the above data my line of treatment should never be neglected until we have a better one to replace it, as I hope and expect will be the case in time. Bone-marrow in tabloids, to repair the blood deterioration, is also of considerable value; arsenic is worthy of trial, while in the form of atoxyl, which is now being advocated in the allied protozoal disease, sleeping sickness, my friend, Captain J. W. D. Megaw, I.M.S., has injected in two cases with at least temporary good effects. Colonel C. P. Lukis, I.M.S., Principal of the Medical College, Calcutta, has also tried citramate of soda to increase the leucocytes, but without accomplishing the desired result or doing any good, while x rays over the spleen have been tried by the same observer, but without effecting any cures. In view of the chronicity of the disease and the occasional remarkable spontaneous recoveries from an apparently hopeless state much caution is required in making deductions regarding any line of treatment, but the extraordinary cures which do occur encourage the hope that a better treatment, even than the quinine one, will be found to rescue these unfortunates from the lingering death which still awaits the great majority of them.

THE DISTRIBUTION OF SPORADIC KALA-AZAR IN INDIA.

Since it became known that so many cases previously classed as "malarial cachexia" are but the sporadic form of kala-azar observations on its distribution have been accumulating. Donovan and others have found it to be very common in Madras, while my own observations have shown it to be widely distributed all over Lower Bengal and Assam, except the eastern part of the Brahmaputra valley, while it also occurs somewhat less frequently in Western Bengal or Bihar, and extends into the neighbouring eastern end of the United Provinces of Agra and Oudh, cases in soldiers having been verified by the officers of the Royal Army Medical Corps at Benares, while I have also seen two soldiers who appear to have contracted the disease in Allahabad, and others have been met with among Gurkhas in as far west as Dehra Dun. On the other hand, during an examination of the records of all the fever cases admitted to the Lahore Medical College Hospital for three years I failed to find any cases resembling sporadic kala-azar, while it is also specially noteworthy that I met with no double remittent, low continued, or other doubtful long fevers among them. The Bombay records also show a similar absence of the disease, except rare importations from Madras, so that the disease appears to be limited to the eastern side of India, although I am informed that Burma, like Bombay, only has cases contracted at Madras.

In connection with this distribution it is of interest to note that the areas affected all have a very mild cold season, during which the mean temperature for three or four months remains between from 60° to 75° F., for I shall show in my concluding lecture that these are the limits between which I have been able to cultivate the parasite outside the human body. On the other hand, in the unaffected north-west parts of India the mean temperature during the cold months falls below 60°, while owing to the brevity of spring and autumn in India the temperature conditions most favourable to the organism outside the human body is a very short one in those areas.

EFFECTS OF SEASONAL VARIATIONS ON THE PREVALENCE AND ORIGIN OF THE DISEASE.

I have already shown that the infection of kala-azar is probably limited to the cold season, so an exceptionally long spell of cold weather might be expected temporarily to increase

will greatly simplify matters if precautions against infection have only to be taken during a few months of the year.

THE TYPES OF FEVER IN KALA-AZAR.

I now come to the difficult subject of the diagnostic value of the types of fever in kala-azar, my conclusions being based on four-hour temperature charts of every case in the European Calcutta Hospital for several years, and a still larger series in native patients, while as I also possess complete notes and charts of every fever case in the open wards of the European Hospital for two years, I am now in a position to point out the most important features in the diagnosis of kala-azar in the difficult early stages from other fevers with which they are commonly confused. The antem slides prepared from the charts, some of which represent the temperature curves for several months, will best serve to illustrate the types met with.

[The principal points illustrated by the charts shown were the following. The very long duration of the fever, which shows alternating remittent and intermittent types for many months at a stretch, even in the case of patients admitted in a markedly cachectic and anæmic condition, showing the great resisting powers of his patients. When the temperature is of the remittent type there are rapid wasting and impoverishment of the blood, but when it falls to the low intermittent type both the weight and the blood show steady improvement, while quinine in large doses has a marked effect in reducing the high dangerous type of fever to the low comparatively harmless one which may eventually wear itself out and cease entirely, and then the weight is soon regained, and once the patient has been free from fever for two or three months and fully regained the normal weight relapses do not occur and recovery is permanent and complete. Such cessation of the fever and cure sometimes follow a severe septic complication, such as cancrum oris, and are then accompanied by a marked rise in the previously very low number of polymuclear leucocytes, which the lecturer has also been able to produce with good results in a few cases by injections of sterilised cultures of staphylococci, in accordance with the methods of Sir A. E. Wright, although this treatment has not been invariably successful. The good effect of large doses of quinine was illustrated by a nine months chart of a child, aged eight years, seen early in the disease, and whose fever was only finally broken when 50 grains of quinine had been taken daily for seven weeks, her weight also steadily rising from the time this large dose was given, no ill effect being produced by it. The recognition of the fever of kala-azar in its early stage, which usually begins with a high remittent form of pyrexia, may often be accomplished by noting certain peculiarities in four-hour temperature charts. The most important of these, which was illustrated by several slides, is what the lecturer has already described as the double remittent type—namely, a marked daily double or triple rise of the temperature, often for several days together, in the absence of any treatment by the more powerful sweat-producing antipyretic drugs such as antipyrin. This double type is most frequently seen in the earlier periods of the fever, but may occur at any time in its course, and may also occasionally appear during continued or intermittent pyrexia in kala-azar. The great importance of this type is that, in the lecturer's experience, it has never been seen in typhoid fever, for which the early stage of sporadic kala-azar is so frequently mistaken, as in some of the cases illustrated, and this type is almost diagnostic of the new fever, the first case in a European in Bombay having been first suspected on account of the double remissions taking place. Another type of fever shown in the lantern slides, which is rather characteristic of this fever, is a low continued type of pyrexia, the temperature falling below 101°F., but not varying more than 2° in the 24 hours; a type which is much rarer in typhoid fever, in which the pulse is also usually slower than in kala-azar in proportion to the degree of the pyrexia. Moreover, even when the fever is high for long periods in kala-azar there is a characteristic absence of severe distress or typhoid symptoms, patients often saying that they feel quite well and do not think they have any fever, when the thermometer registers 103° or 104°. Once more, when the remittent temperature falls it commonly assumes a low intermittent type, rising to about 100° every afternoon, instead of running a subnormal course as after typhoid fever, a feature that will often allow of the more serious kala-azar being suspected at an early date before the cachectic stage has been reached. A consideration of these various types will nearly always allow of the

sporadic affection being suspected at an early date, when persistent treatment is most likely to be of avail, while the blood changes will allow of the diagnosis being confirmed.]

THE SPLEEN AND LIVER IN KALA-AZAR.

Time will not allow of my giving a full clinical account of this remarkable disease (although I hope to do so shortly in a work on Fevers in India, for which I have been collecting material for a number of years), but a few more of the salient points must be touched on.

The spleen.—The great degree of enlargement of the spleen can best be indicated by the following data. In 70 typical advanced cases of the epidemic disease in Assam of which I have notes the spleen was enlarged in all, while in 94.5 per cent. it reached to at least three inches below the costal margin, in 56.5 per cent. it extended to the navel or beyond, while in 27.7 per cent. to the level of the anterior superior spine of the ilium. In 95 consecutive sporadic cases in the Medical College, Calcutta, all verified by finding the parasite in the spleen blood, in 80 per cent. the organ reached to the navel or beyond and in 10 per cent. to the anterior superior spine of the ilium. In a series of earlier sporadic cases at the European General Hospital the spleen extended to the navel or beyond in 63 per cent., being nearly always of this size in cases of over three months duration, although the edge was above the navel in three-fifths of the cases with under one month's history of fever. On the other hand, among 200 healthy coolies I examined in Assam on a tea garden when unaffected with kala-azar I found only 1 per cent. with spleens reaching down to the navel, in only 6 per cent. did it extend three inches below the ribs, while in a total of 25 per cent. the organ could be felt below the ribs—figures which suffice to disprove Dr. G. M. Giles's statement that it would be absurd to attach any importance to enlargement of the spleen in kala-azar in such a malarious country as Assam.

The liver.—This organ was enlarged in 93 per cent. of my Assam series, in 75 per cent. of the Medical College, and in 59 per cent. of the European cases in Calcutta, who came earlier under observation, it having been normal in seven-eighths of these European patients admitted during the first month of the fever. The enlargement of the liver to any marked degree is very uncommon in the earlier stages, although after some months it may occasionally reach down to the navel and may then be even larger than the spleen, and eventually become cirrhotic, causing ascites.

The blood changes.—I have elsewhere described the blood changes in kala-azar and pointed out their great value in differentiating it from other diseases, especially fevers, so need only now summarise them. In the first place, an increase in the percentage of the large mononuclear leucocytes is very common and of great value as a point in the differentiation of the early stages of sporadic kala-azar from typhoid fever, for in the latter the lymphocytes, but very rarely the large mononuclears, are increased during the pyrexia. On the other hand, this change is of no help in distinguishing kala-azar from true chronic malaria, in which a large mononuclear increase is also commonly present. These two last diseases may, however, be distinguished by counting the total red and white corpuscles and working out the proportion between the two, for in malaria both are about equally reduced, so that the ratio of white to red remains normal—namely, about 1 to 750—and very rarely, if ever, falls below 1 to 1000, while in kala-azar it is the rule for the white corpuscles to be disproportionately reduced, so that the ratio of white to red is, in the absence of any leucocyte-increasing complication, commonly below 1 to 1500, and not rarely as low as 1 to 2000, 3000, or more. This extraordinary reduction of the leucocytes, which is rarely number but from 500 to 1000 per cubic millimetre, is almost diagnostic of kala-azar, as I have never met them in any other fever cases out of several scores in which I have done blood counts, and it has often enabled me to diagnose the disease in a comparatively early stage. So much is this the case that I now rarely employ the spleen puncture as a diagnostic measure, several fatal cases in addition to those published having come to my knowledge. It should never be done in very anæmic patients or in those who have suffered from any form of hæmorrhage unless the blood is first proved to be clotting normally, while I always take the further precaution of keeping up digital pressure for several minutes after withdrawing the needle and immediately administering a dose of calcium chloride by the mouth. With these precautions it may be of value in some difficult comparatively

the occurrence of the disease. This is actually so, for two years ago such a cold season occurred in Bengal, and during it and the following early hot weather months an unusually large number of sporadic kala-azar cases were admitted to both the native and European hospitals of Calcutta, many more than in the following year with a normal cold season. Now this long spell of cold weather followed an early cessation of the previous monsoon rains, for the withdrawal of the south-west monsoon is succeeded by a cold north breeze, and it will be remembered that in my first lecture I pointed out that the Assam epidemic arose as a consequence of four out of five successive years of deficient rainfall in the early "seventies," due to an early cessation of the monsoon current. I have not been able to get complete meteorological data for the Rungpore district in the "seventies," but those of Calcutta of that period show that during several of the years of deficient rain the mean temperatures of the ensuing cold season were below the average. Now, if a single cold year had such a marked influence in increasing the sporadic kala-azar in Calcutta, on account of the longer period which was favourable to the infection, it becomes easy to understand how an unusual succession of such seasons might have increased the number of cases, and so the foci of infection, year by year, until the fever became so widespread that the people began to leave their villages and thus carried the infection into areas at the foot of the Garo hills and in the Goalpara subdivision, which had hitherto been almost or quite free from it, and so started the spreading of the disease in Assam in a people who were extremely susceptible to it owing to not having previously suffered from the sporadic form. Such an origin of the Assam epidemic of kala-azar is most in accordance with the known facts of its history, and also with the life-history of the parasite and mode of infection, which I shall deal with in my remaining lecture.

ABSTRACT OF

The Morrison Lectures

ON

INSANITY, WITH SPECIAL REFERENCE TO PROGNOSIS.

Delivered before the Royal College of Physicians of Edinburgh on Jan. 28th and 30th and Feb. 1st, 1907,

By A. R. URQUHART, M.D. ABERD.,
F.R.C.P. EDIN.,

PHYSICIAN-SUPERINTENDENT, JAMES MURRAY'S ROYAL ASYLUM,
PERTH.

LECTURE I.¹

Delivered on Jan. 28th.

IN no kind of disease is prognosis more doubtful than in insanity. For long overshadowed by ignorance and superstition, for long regarded as a mysterious calamity, for long obscured by confusing issues, it is only of late years that the fundamental truths have been disengaged from the fantastic phenomena which formerly dominated the attention of the observer. The long-drawn melancholy, the violent excitement, the bizarre ideas, and the dangerous conduct of the insane wholly occupied attention and precluded the study of obscure and elusive bodily conditions. The tedious recital of aberrant talk and morbid conduct long detained us with mere irrelevancies. It is unnecessary to discuss the history of medical literature dealing with insanity, until the memorable publication of Schroeder van der Kolk's lectures on Mental Diseases, which took shape about the middle of last century. He arrived at the conclusion that much insanity is due to morbid conditions of the great intestine. In accordance with the medical ideas of his time he described this class of cases as "sympathetic insanity." While he clearly recognised the brain as the organ of mind, he believed that it is liable to disturbance in direct consequence of somatic conditions, influencing it in a secondary manner. This conclusion was widely supported, and here in Edinburgh the influence of the body on the mind was

definitely fixed and crystallised by Skae's classification of mental diseases.

It is almost impossible to gain any useful information from old asylum records. In the earliest series the recorders note the reception of a lunatic and briefly indicate that he was furious or fatuous, sometimes adding an account of heroic doses of medicaments, blistering, and bleeding, and sometimes an indication of removal by death or otherwise. At a later period the cases are described as psychological curiosities—how they arrived on foot or in a carriage, how they displayed their morbid ideas, how they wrote, and how they behaved. But withal the most chary record of physical disorders, the most elusive statements as to family or personal history—in brief, it was the study of mind apart from body—the psychological content. Having arrived at the conclusion that there is no pathology of insanity comment on somatic conditions was, of course, superfluous.

The blood of the insane is the *denier ori* of the modern investigator. Dr. Lauder Lindsay, so long ago as 1854, published a series of observations on the histology of the blood of the insane, which he had made in the Orichton Royal Institution. He did not claim that his researches elucidated the morbid conditions of mind, or its organ, the brain; but rather illustrated the laws of pathology, the natural relations of healthy and morbid states of mind and body, and more particularly the reaction of physical diseases on mental phenomena. The *résumé* was presented under 14 headings, the fourth being to the effect that a leucocytæmic condition frequently exists. As examples of this, cases of general paralysis, acute mania, and melancholia are cited. Unfortunately, Dr. Lindsay concluded that there was no connexion between the state of the blood and the mental condition, but that it bore a relation to the physical disorder, debilitated conditions of the system, and general vitiation of the blood.

Thirty years elapsed before another systematic investigation of the blood of the insane was undertaken, when Dr. S. R. Macphail in 1884 won the medal of the Medico-Psychological Association. By that time the hæmocytometer and the hæmoglobinometer had been invented and with these instruments of precision further advance was recorded. In general paralysis Dr. Macphail recorded an increase in the relative proportion of white to red corpuscles, coincident with the progress of the disease; he failed to find any great influence on the proportion of white to red corpuscles in maniacal attacks, while in a series of recent admissions the proportion was increased. Most important is his conclusion that there is a close connexion between gain in weight, improvement in the quality of the blood, and mental recovery.

Another prize essay on the same subject was the work of Dr. Johnson Smyth in 1890. He inferred that the relative proportions of white to red corpuscles were so variable as to be of little importance. In many instances, however, he recorded an excess of leucocytes and stated that the blood of the insane is in a pathological condition.

Quite recently the position has been still further developed by the researches and conclusions of yesterday. Within the last few months Dr. L. O. Bruce has published his records of clinical investigations. Much of his book is concerned with observations on the blood of the insane, and specially on the leucocytosis which he has shown to be of definite importance in diagnosis and prognosis. What was dimly discerned by Dr. Lauder Lindsay half a century ago is made clear by Dr. Bruce to day, and especially the important conclusion that the morbid state of the blood is a dominating factor in the evolution of mental diseases. Sufficient has been said to indicate the growth of medical opinion relevant to insanity as an affair of medicine. Similar references might be made to other somatic conditions the true nature of which is only now intelligible and explicable. I have referred to Schroeder van der Kolk as one of the first to appreciate the toxic nature of insanity. He said: "It is evident that the brain, as the organ through which the higher intellectual powers are immediately manifested, must especially suffer in insanity. We should, however, be much in error in seeking the proper source and cause of the disease always in the brain, for the influence which many organs exercise upon the brain is evident enough." The Hippocratic doctrine that insanity is caused by disease had been obliterated by the superstition of the Middle Ages. The brain, as the organ of mind, infinitely complex in its own proper connexions, is at present the subject of study relative to its relations with all pathological somatic conditions. Thus the sympathetic insanity of van der Kolk is regarded as a toxic

¹ The lectures were illustrated by statistical tables, charts, and clinical observations.

Pearson will greatly enlarge our knowledge and correct our prepossessions, if the desirable data are forthcoming. We only require a collection of accurate facts in sufficient numbers to correct the margin of error.

SOME OBSERVATIONS ON UTERINE FIBROIDS:

BASED ON A SERIES OF 150 CONSECUTIVE CASES TREATED BY ABDOMINAL OPERATION.¹

By ARTHUR E. GILES, M.D., B.Sc. LOND., F.R.C.S.
EDIN.,

SURGEON TO THE CHELSEA HOSPITAL FOR WOMEN; GYNÆCOLOGIST TO THE TOTTENHAM HOSPITAL.

I.

WHEN discussing such a subject as uterine fibroids the greatest risk that one runs is that of becoming too discursive, because there are so many aspects of the subject that are full of interest and importance. In order to minimise this risk I propose to confine my remarks to a few points, as exemplified by cases that have come under my own observation, and upon whom I have had occasion to perform an abdominal operation. The text or basis of my paper is therefore a consecutive series of the first 150 cases so treated spread over a period of 11 years.

The points that I wish to consider are the following: 1. The age-incidence of fibroids. 2. The relation between fibroids and sterility. 3. Indications for operation as based upon (a) the symptoms produced; and (b) the complications to which fibroids are liable. 4. Methods of operation in relation to varieties of fibroids.

1. THE AGE-INCIDENCE OF FIBROIDS.

An examination of the ages of the patients at the time of operation gives the following results:—

Age.	Number of cases.	Age.	Number of cases.
Under 25 years	1	45-49 years	42
25-29 years	3	50-54 "	16
30-34 "	21	55-59 "	4
35-39 "	20	60 years or over	
40-44 "	41		

Or, expressed in decades:—

Age.	Number of cases.	Percentage.
Under 20 years	0	0.0
20-29 years	4	2.66
30-39 "	41	27.33
40-49 "	83	55.33
50-59 "	20	13.33
60 years or over	2	1.33
	150	100.0

These figures are in harmony with the general view that fibroids are almost unknown under 20 years and rare under 30 years; they are met with not infrequently between the ages of 30 and 40 years, and between 40 and 50 years they are relatively common. It must be noted that these figures do not express the age of onset of fibroids, because many of the patients had been the subjects of these tumours for years before they were operated upon; nor do they represent the relative ages of all patients suffering from fibroids; their more precise significance is the age at which the fibroids in my cases gave rise to such troubles as called for operation. The reason that the numbers rapidly diminish after the age of 50 years and drop almost suddenly after 60 years is that by this time the majority of patients have been operated upon nowadays, whilst some have died from the complications of fibroids, and some have been enabled, by the absence of complications or serious symptoms, or by putting up with a life of semi-invalidism, to retain their tumours undisturbed by the surgeon's knife. The youngest patient on this list was No. 11; she was 23 years old, and operation was necessitated by profuse hæmorrhage. The two oldest patients, Nos. 31 and 42, were aged 63 years, the one a single woman and the other a widow; both required operation on account of

pressure symptoms, amounting, in the case of the latter, to partial intestinal obstruction.

I have examined my cases to see if there be any relation between the age of patients and the characters of their tumours and the results are set forth in the following table:—

Variety of tumour.	Under 30 years.	30-34 years.	35-39 years.	40-44 years.	45-49 years.	50-54 years.	55-59 years.	60 years and over.	Total.
Simple fibroids	1	4	7	12	13	7	2	0	46
Multiple fibroids	0	7	7	16	18	5	2	1	56
Cervix fibroids (solitary) ...	1	2	1	1	0	0	0	0	5
Subperitoneal fibroids* ...	0	6	3	1	2	1	0	0	13
Interstitial fibroids*	0	1	1	6	2	0	0	0	10
Submucous fibroids*	1	1	0	0	1	0	0	0	3
Soft red fibroid	1	0	1	0	1	0	0	0	3
Fibroids with cystic or necrotic degeneration	0	0	0	5	5	3	0	1	14
Totals	4	21	20	41	42	16	4	2	150

* Conditions allowing of myomectomy instead of hysterectomy.

We cannot lay great stress on this table because the numbers are too small, but it appears evident that the age of patients does not materially influence the character of the tumours, except in the matter of degenerative changes, which are strikingly absent before the age of 40 years. This, of course, is what we should expect from the life-history of fibroids.

2. THE RELATION BETWEEN FIBROIDS AND STERILITY.

It has long been known that there is a close association between sterility or arrested fertility and fibroids, and it occurred to me that it would be a matter of interest to endeavour to ascertain the precise nature of that association. It may be said briefly that the relation appears to be not between fibroids and sterility—i.e., incapacity to conceive—but between fibroids and the absence of pregnancy, whether the patient has had the opportunity of conceiving or not. I shall first state the facts at our disposal, derived from an analysis of these cases, and then make some rather speculative observations by way of inference. Of the 150 patients operated upon, 56 were single women and 94 were married. Of the 94 married women, 34 had never been pregnant and 60 had borne children. Thus the total number who had not been pregnant was 90, and our first deduction is that in 60 per cent. of cases of fibroids the patient has not been pregnant.

The length of time that the nulliparae had been married was as follows, the time being not stated in my notes in 11 cases:—

Under 1 year	3 cases.	7 years	1 case.	18 years	1 case.
2 years	1 case.	9 "	1 " "	20 "	1 " "
3 "	2 cases.	12 "	1 " "	24 "	1 " "
4 "	2 " "	13 "	2 cases.	28 "	1 " "
6 "	2 " "	17 "	3 " "	33 "	1 " "

When we investigate the cases of women who had borne children we obtain some interesting and striking results. In the next table I have drawn up a list showing the number of pregnancies that each patient had had and the number of years that had elapsed since the last pregnancy. In my notes the data concerning the number of pregnancies are wanting in three cases, and the length of time since the last confinement in six cases.

Omitting the last three cases on the list, where the number of pregnancies was not known, 57 patients had had between them 172 pregnancies, giving an average of three pregnancies to each patient. Of these 172 no fewer than 38 had terminated in miscarriages. On glancing at the list one is struck by the relatively large number of patients who had had only one or two pregnancies—namely, 27 out of 57. Our second deduction is that among married women fibroids are associated with diminished fertility. But perhaps the most notable feature about this list is the long time, in the majority of cases, that had elapsed since the last pregnancy. Data are wanting on this point in six out of the 60 cases, and of the remaining 54 three were pregnant when first seen;

FIG. 3, Typical cervix fibroid, from Case 95. FIG. 4, Cervix fibroid growing into the left broad ligament, from Case 6. FIG. 5, Cervix fibroid growing downwards into the vagina, from a case of vaginal myomectomy, from Case 60. FIG. 6, Subperitoneal fibroid of the uterine cornu, from Case 62. FIG. 7, Pedunculated subperitoneal fibroid of the fundus, from Case 40. FIG. 8, Pedunculated subperitoneal fibroid of the fundus, from Case 34. FIG. 9, Pedunculated subperitoneal fibroid of the fundus, from Case 34. FIG. 10, Subperitoneal fibroid of the fundus, from Case 34. FIG. 11, Subperitoneal fibroid of the fundus, from Case 34. FIG. 12, Submucous fibroid, removed by hysterotomy, from Case 32. FIG. 13, Pedunculated submucous fibroid of the fundus, from Case 32. FIG. 14, Multiple uterine fibroids, from Case 24. A case of vaginal myomectomy.

General disablement—that is, weakness, inability to walk or to work—was a marked feature complained of in 14 cases. In many of the other cases there was more or less disablement. In the case of one patient there were virtually no symptoms at all except some frequency of micturition. She married a medical man who discovered the tumour and brought her to me on the day after the marriage. As they were going to reside abroad they both desired that the tumour should be removed forthwith and this was done on the fourth day after marriage.

(6) *The complications to which fibroids are liable.*—Complications may affect the tumours, the uterus, the ovaries and tubes, or adjacent structures. That they are very frequent is shown by the fact that some complication was present in 84 out of 150 cases, or 62 per cent. I shall consider them in the order given.

Tumours.—Uterine fibroids, like ovarian tumours, are liable to the accidents of impaction in the pelvis and torsion of the pedicle. Impaction may be brought about in three ways: in the first place, by a cervix fibroid, which must necessarily, in the course of its growth, fill up the true pelvis, since its position precludes it from rising into the abdomen. This occurs both with the typical solitary cervix fibroid, of which I had three instances, and also with multiple fibroids when one of them is cervical, of which there were four instances; but with a solitary cervix fibroid growing into the broad ligament, which was met with in two cases, it does not necessarily happen, because the broad ligament allows of expansion into the abdomen. Secondly, impaction may occur when a pedunculated fibroid falls into the true pelvis and continues to develop there. This occurred in three cases; in one of them it contracted adhesions and gave rise to dystocia. Thirdly, impaction results when a uterus which is the seat of fibroids becomes retroverted, and the tumour is large enough to fill the pelvis. Of this, there was one instance (Case 44), the tumour forming virtually a cast of the pelvis. The physical signs in such a case resemble retroversion of the gravid uterus at the third month, except that the mass is harder than it is in pregnancy, and there are corresponding bladder-troubles—namely, first frequency of micturition and then retention of urine. Twisting of the pedicle is necessarily a rare accident, because only few pedunculated fibroids have a pedicle small enough in proportion to their size to allow of rotation. It occurred in one case (No. 40).

FIG. 1.

A macerated calcified fibroid removed by vaginal myomectomy; natural size.

More important, because more frequent, are the secondary changes to which fibroid tumours are liable. They may undergo a myxomatous change, leading to the so-called fibrocystic tumour, of which there were seven examples. If

such a tumour be submucous in position septic infection may occur. In other cases, numbering eight in our series, necrobiotic changes supervene, due, in all probability, to the partial cutting off of the blood-supply. When such a tumour is in the position of an intra-uterine polypus the uterus tends to expel it towards or into the vagina, and by compression of the pedicle the necrotic changes become accentuated, so that we have the "sloughing fibroid polypus." This condition was present in one case. Another change that takes place is the calcification of tumours. In one case (No. 45) a number of the tumours were more or less calcified. The extremes to which the process may go are well shown in the specimen I have here (Fig. 1); it did not occur in a case in this series, because it was removed by vaginal myomectomy. The case is referred to later, when speaking of this operation. The calcification was so complete that it was a matter of considerable time and labour to saw it across.

FIG. 2.

Fibroma of the ovary associated with uterine fibroids.

The uterus.—A fibroid uterus is liable to two important complications—namely, retroversion and pregnancy. Of retroversion we have 11 instances; in three of these the uterus was fixed by adhesions and one of them was the case of impaction previously referred to. Pregnancy complicated four of my cases. One (No. 8) was a case of cervical fibroid in the broad ligament, in which delivery by the natural passages would have become impossible. Another (No. 93) was a case of missed abortion. The third (No. 33) was the case of dystocia spoken of previously; the fibroid arose from the posterior wall of the uterus low down and was adherent in the hollow of the sacrum. The condition was not discovered until after labour had begun, because there had been no symptoms. When the labour made no progress her medical attendant turned the child and brought down a leg and then discovered the tumour. As it was evident that delivery by the natural way was impossible, the patient was sent into the hospital and a Caesarean hysterectomy was performed. The fourth case (No. 39) was six months' pregnant when she was first seen and she had a good-sized sessile fibroid high up on the posterior wall of the uterus. It was thought that she could safely await her confinement without interference; labour came on prematurely, however, and a myomectomy was done six weeks later.

The ovaries and tubes.—These organs were diseased in 59 cases, or 40 per cent. It appears that the ovaries are rather prone to cystic degeneration in cases of fibroids, this condition accounting for 33 cases of which 12 had both ovaries and 21 had one ovary affected. That is, some ovarian cystic degeneration was present in 1 case in every 5. Ovarian tumours were present in 16 cases, as follows: Three patients

experienced operators. In some cases, however, and especially when the cervix is the seat of tumours or raises suspicions of malignancy, it is better to remove the whole uterus, including the cervix. This operation is known as total hysterectomy or panhysterectomy.

In this series a hysterectomy was done 120 times—namely, subtotal hysterectomy in 109 cases and total hysterectomy in 11. In many cases the appendages had to be removed also, the exact operations and the number of each performed being as follows:—

Oophorectomy	3
Abdominal myomectomy—	
Subperitoneal	11
Interstitial	13
Submucous	3—27
Abdominal hysterectomy—	
Both appendages left	33
Appendages of one side removed	41
Appendages of both sides removed	35—109
Panhysterectomy—	
Both appendages left	3
Appendages of one side removed	4
Appendages of both sides removed	4—11

150

CONCLUSION.

I have reviewed at some length the somewhat formidable list of disabling symptoms and organic complications that follow in the train of fibroids, and if I have incurred the risk of taxing the reader's patience therewith my excuse must be that such a course was necessary in order to demonstrate that these tumours are by no means so innocent and harmless as they have been represented to be. When I began practice I was disposed to regard fibroids with leniency, but a closer acquaintance with them has led me to regard them as dangerous to life and seriously inimical to health and usefulness, and I feel that this position is justified by the facts which I have placed on record. I do not claim that there is anything original in my point of view, for nearly all those who have had an operative acquaintance with fibroids have come to the same conclusion. I am not engaged in slaying an obsolete idea, for even in this progressive day the venerable tradition that fibroids are comparatively harmless possessions is endowed with a considerable, though diminishing, vitality. I have no quarrel with venerable traditions as such, but when they become mischievous they require to be extinguished—mercifully, if possible, but in any case extinguished. There was a time when this same tradition, which is now mischievous, was actually beneficent—a time, namely, when operations for the removal of fibroids were attended by such a high rate of mortality that the cure was even more dangerous than the disease. Then it was wise to teach that they should be generally left alone. As operative results improved, the tradition, instead of being actively beneficent, became merely innocuous; but with further progress of such a sort that patients can be restored to health and usefulness with greatly diminished risk, it is a cruelty to condemn them to suffer on the strength of a tradition which is directly contrary to fact. To-day the risks of operations for fibroids arise chiefly out of serious complications, and if we act upon the principle of removing fibroids as soon as they give trouble, without waiting until the onset of dangerous complications, the operative mortality will fall as low as that of ovariectomy. I am solemnly convinced that the interests of our patients demand the general acceptance of this principle, and that with the inexorability of fate the principle will be accepted sooner or later, whether we help it or hinder. Therefore, regardless of possible charges of *furor operaticus* or *cacoethes operandi*, I invite the medical profession to approve the principle and to combat the tradition.

LIST OF CASES.

In the following list the particulars of each case are stated in the following order:—Consecutive number; patient's initials, age, and civil state; place of operation (C.H.W.=Chelsea Hospital for Women; T.H.=Tottenham Hospital; P.=private case); date of operation; condition at the time of operation; particulars of operation; result (R.=recovery, D.=death); remarks, if any.

- 1.—C.W., 45, W.; C.H.W.; 1895, Sept. 5th; uterine fibroids; double oophorectomy; R.
- 2.—G.R., 31, S.; C.H.W.; 1896, Oct. 2nd; uterine fibroid; double oophorectomy; R.
- 3.—M.C., 35, S.; C.H.W.; 1897, July 22nd; multiple uterine fibroids; abdominal hysterectomy and removal of the right appendages; R.
- 4.—A.C., 42, M.; C.H.W.; 1893, April 18th; uterine fibroid, left ovarian dermoid, right hydro-salpinx; double ovariectomy; R.
- 5.—E.H., 29, M.; C.H.W.; Sept. 2nd; broad ligament fibroid, arising from the cervix; abdominal hysterectomy, removal of left appendages; R.

- 6.—E.O., 46, S.; C.H.W.; Sept. 26th; uterine fibroid; abdominal hysterectomy, removal of left appendages; R.
- 7.—L.T., 40, S.; C.H.W.; Dec. 12th; multiple uterine fibroids; abdominal hysterectomy; R.
- 8.—O.J., 35, M.; C.H.W.; Dr. G. W. F. Macnaughton; 1899, Oct. 30th; broad ligament fibroid arising from the cervix, pregnancy 4 months; (n) abdominal myomectomy, secondary hemorrhage; (9) reopening, abdominal hysterectomy; D., pneumonia (third day).
- 9.—K.V., 46, M.; P.; Dr. A. S. Gubb; Nov. 3rd; uterine fibroid, umbilical hernia; abdominal hysterectomy, radical cure of hernia; R.
- 10.—A.R., 40, S.; T.H.; 1900, August 14th; large pedunculated uterine fibroid; abdominal myomectomy; subsequent hysterectomy in May, 1906. (See No. 132.)
- 11.—M.H., 23, S.; P.; Dr. P. R. Dodwell; August 31st; intra-uterine fibroid; abdominal myomectomy by hysterotomy; R. Case reported in London Obstetrical Transactions for 1900.
- 12.—R.G., 35, S.; C.H.W.; Sept. 10th; uterine fibroid, left ovarian cyst, right ovarian dermoid; abdominal hysterectomy, double ovariectomy; R.
- 13.—E.S., 47, S.; C.H.W.; Sept. 17th; large uterine fibroids (17 pounds), both ovaries cystic and flattened by tumour; abdominal hysterectomy, double ovariectomy; R.
- 14.—S.S., 30, M.; C.H.W.; Sept. 17th; uterine fibroid; abdominal hysterectomy; R.
- 15.—F.H., 45, M.; C.H.W.; Sept. 24th; uterine fibroid; abdominal hysterectomy; R.
- 16.—M.S., 43, M.; T.H.; Dr. R. B. Marjoribanks; 1901, Jan. 15th; multiple uterine fibroids, diseased appendages; abdominal hysterectomy, both appendages removed; R.
- 17.—M.D., 51, S.; T.H.; March; multiple uterine fibroids; diseased appendages; abdominal hysterectomy; both appendages removed; R.
- 18.—L.I., 51, M.; C.H.W.; April 1st; uterine fibroid, right hydro-salpinx; abdominal hysterectomy; both appendages removed; R.
- 19.—B.N., 56, M.; T.H.; April 23rd; uterine fibroid; abdominal hysterectomy; D.
- 20.—C.H., 32, M.; C.H.W.; June 10th; uterine fibroid; abdominal hysterectomy; R.
- 21.—S.B., 36, M.; P.; Dr. J. W. MacVine; June 21st; uterine fibroid; abdominal hysterectomy; R.
- 22.—M.S., 35, M.; T.H.; June 24th; interstitial fibroids, in fixed retroverted uterus; abdominal myomectomy by enucleation, ventro-fixation; R.
- 23.—R.R., 43, M.; T.H.; July 2nd; large uterine fibroids; ovaries both cystic; abdominal hysterectomy; double ovariectomy; R.
- 24.—L.O., 40, S.; T.H.; August 6th; uterine fibroid; abdominal hysterectomy; R.
- 25.—A.H., 46, M.; T.H.; Dr. C. E. Hutt; Oct. 24th; interstitial fibroid in fixed retroverted uterus; abdominal myomectomy by enucleation, ventrofixation; R.
- 26.—E.H., 33, M.; T.H.; Dr. C. H. Adamson; Oct. 24th; large uterine fibroid attached to fundus, several interstitial fibroids, adhesion of bladder on left side of fundus; abdominal hysterectomy, right ovariectomy; R.
- 27.—E.W., 62, M.; C.H.W.; Nov. 24th; uterine fibroid impacted and adherent in pelvis, right ovarian dermoid; abdominal hysterectomy, right ovariectomy; R.
- 28.—E.O., 53, S.; T.H.; Nov. 28th; uterine fibroid, right ovarian blood cyst; abdominal hysterectomy, removal of right appendages; R.
- 29.—E.E., 53, S.; T.H.; Dec. 17th; uterine fibroid in uterus septus; abdominal hysterectomy; removal of right appendages; R.
- 30.—A.B., 46, M.; T.H.; Dr. J. W. MacVine; 1902, Feb. 13th, uterine fibroid, right ovary cystic; abdominal hysterectomy, removal of right appendages; R.
- 31.—L.I., 63, S.; T.H.; Dr. R. B. Marjoribanks; Feb. 20th; pedunculated cystic uterine fibroid, right cornu; three smaller fibroids; abdominal myomectomy; R.
- 32.—P.T., 31, M.; T.H.; Dr. David Petty; April 10th; intra-uterine fibroid of size of fist; abdominal myomectomy by hysterotomy; R.
- 33.—T.H., 31, M.; T.H.; Dr. C. E. Hutt; April 17th; large uterine fibroid obstructing labour at full term; Caesarean hysterectomy, removal of right appendages; R.
- 34.—A.S., 41, S.; T.H.; Dr. J. Thoresby Jones; May 22nd; large degenerating cystic fibroid, attached to anterior wall of uterus; abdominal myomectomy; R.
- 35.—E.S., 47, M.; T.H.; Dr. C. E. Hutt; May 22nd; multiple uterine fibroids; abdominal hysterectomy; removal of left appendages; R.
- 36.—R.H., 32, M.; C.H.W.; Dr. J. B. Wallace; June 16th; multiple uterine fibroids, right ovary cystic; abdominal hysterectomy, removal of right appendages; R.
- 37.—S.M., 47, S.; T.H.; Dr. Horace R. Wilson; June 19th; multiple uterine fibroids; abdominal hysterectomy; R.
- 38.—L.S., 51, M.; T.H.; August 28th; multiple large uterine fibroids; both ovaries cystic; abdominal hysterectomy removal of both appendages; R.
- 39.—M.C., 39, M.; T.H.; Dr. P. P. Elliott; Sept. 4th; sessile sub-peritoneal fibroid, posterior surface of uterus; myomectomy by enucleation; R.
- 40.—R.G., 49, S.; C.H.W.; Dr. A. Irby Webster; Sept. 8th; multiple uterine fibroids, a large pedunculated fibroid of the fundus with twisted pedicle; abdominal hysterectomy, removal of both appendages; R.
- 41.—M.E., 43, M.; C.H.W.; Dr. A. H. Hoffman; Sept. 8th; cervical fibroid of size of large fist, in supravaginal portion; abdominal hysterectomy; R.
- 42.—E.D., 63, W.; T.H.; Dr. O. R. Salisbury; Sept. 11th; multiple uterine fibroids; abdominal hysterectomy; removal of right appendages; R.
- 43.—E.T., 22, M.; T.H.; Sept. 11th; multiple uterine fibroids; abdominal hysterectomy; removal of right appendages; R.
- 44.—E.A., 43, W.; C.H.W.; Dr. J. M. Ehrhardt; Sept. 29th; uterine fibroid, retroverted and forming cast of pelvis; abdominal hysterectomy; R.
- 45.—L.C., 33, S.; T.H.; Dr. J. Cater; Oct. 9th; multiple calcified uterine fibroids, one fibroid situated low in posterior wall of cervix; abdominal hysterectomy; D.
- 46.—M.R., 30, M.; P.; Dr. H. K. Ramadan; Oct. 12th; two sessile fibroids on posterior wall of fundus; uterus retroverted and fixed; abdominal myomectomy by enucleation, ventrofixation; R.
- 47.—E.H., 30, M.; T.H.; Dr. Hugh Silver; Oct. 16th; multiple

had dermoid cysts, and one of these had a multilocular ovarian and another had a hydrosalpinx on the other side. Four had a multilocular ovarian cyst on one side, one of whom had a hydrosalpinx on the other side; one (No. 144) had a large multilocular cyst on each side, complicated by dense adhesions. One (No. 102) had double ovarian papilloma; one had an ovarian fibroma (No. 47): this is shown in Fig. 2; one an ovarian sarcoma (No. 99) and she has since had recurrence in the cellular tissue on both sides of the pelvis. Two had ovarian carcinoma (Nos. 96 and 112); they have so far remained free from recurrence, although the second of them had secondary deposits both in the broad ligament and on the back of the uterus at the time of the operation. The specimen is among those shown. Three patients had cysts with intracystic hæmorrhage, and in one of these cases the cyst had a twisted pedicle. In seven cases there was double salpingitis. Hydrosalpinx of one side was present in one case besides the two previously mentioned, double hydrosalpinx in two cases, unilateral pyosalpinx with acute peritonitis in one case, which proved fatal.

Adjacent structures.—Under this heading may be included cases in which there was localised chronic peritonitis, leading to adhesions to surrounding organs. There were 15 of these, and in some of them the adhesions were very dense, involving the bowel and the bladder, and greatly increasing the operative difficulties. Lastly, there were independent complications in six cases—namely, carcinoma of the sigmoid (two), appendicitis (two), umbilical hernia, and recto-vaginal fistula.

4. METHODS OF OPERATION IN RELATION TO VARIETIES OF FIBROIDS.

Fibroids present such varieties that they require to be dealt with by different operative procedures, and we shall best appreciate these operations by first making a rapid review of the possible conditions met with. I have endeavoured to illustrate some of these by rough outline drawings representing the type of tumour in some of my cases.

Cervix fibroids.—This is a variety to which my colleague Mr. J. Bland-Sutton has drawn special attention; he finds that they occur in about 5 per cent. of cases. Three types are found. The first (Fig. 3) is that in which the fibroid develops in the supravaginal portion of the cervix and forms an ovoid tumour, on the top of which is perched a normal-sized uterine body. This was met with in Cases 41, 95, and 108. Sometimes such a tumour is found associated with other fibroids, as in Cases 45, 98, 109, and 136. The second type (Fig. 4) is one in which the tumour grows out into the broad ligament, remaining attached to the cervix by a pedicle. It corresponds to the subperitoneal fibroid that arises from the body of the uterus. Cases 5 and 8 presented this form of tumour. In the third type (Fig. 5) the fibroid grows downwards into the vagina; such a tumour is removed by vaginal myomectomy.

Fibroids of the body of the uterus are recognised as falling into three categories, the subperitoneal, the interstitial, and the submucous. Subperitoneal fibroids are shown in Figs. 6 to 11. They may have a very broad attachment, as in Figs. 10 and 11; a very narrow one, as in Fig. 6 (where the pedicle was twisted, Case 40); or the attachment may be intermediate in size. Such a tumour as that shown in Fig. 8 produces a remarkable distortion of the uterus. Interstitial fibroids are frequently small, as in Fig. 6; when they get large they tend to assume the subperitoneal or submucous position. Submucous fibroids are shown in Figs. 12 and 13; their tendency is to become polypoid, and the uterus then makes an effort to expel them, as occurred in the case represented in Fig. 13; so vigorous was the effort in this case that a partial inversion of the fundus resulted. Combinations of the three forms are not infrequent, and then we get such tumours as are shown in Fig. 14. Subperitoneal fibroids are specially prone to degenerative changes; submucous fibroids are the ones chiefly responsible for excessive hæmorrhages, and they are particularly liable to septic infection and to sloughing. Interstitial fibroids partake of the characteristics of the other two forms, and all three are apt to cause serious pressure-effects.

It is obvious that so many forms of tumour cannot all be dealt with in a uniform manner. Formerly the practice of removing the ovaries and leaving the tumour was in vogue; that was a time when the mortality of hysterectomy was considerable. I adopted it in three cases, Nos. 1, 2, and 4, but I have not done a case of this kind since early in 1898. The practice has now become obsolete, so I need not take up

time in recapitulating its disadvantages. We have the choice of two routes in dealing with fibroids—namely, the vaginal and the abdominal.

The vaginal route has a limited usefulness. It is, of course, the only way of removing fibroids lying in the vagina, as in Figs. 5 and 13, and it is sometimes useful for the removal of small fibroids in the uterus. For this purpose the cervical canal is dilated and the tumour is removed entire or after cutting it into fragments (*morcellement*). Such procedures are known as vaginal myomectomy. Tumours as large as a golf-ball are often best removed by this method. When the tumour is larger I do not advocate this plan, as I think that it involves more risk and causes much more hæmorrhage than the procedure which I shall refer to as hysterotomy. Sometimes a small tumour imbedded within the wall of the uterus may be removed by vaginal enucleation; the mucosa and capsule over the tumour are incised and the tumour is shelled out. In one of my early cases some ten years ago I attempted this procedure, but found that the tumour was too large and firm to enucleate; I left it hoping that it would become extruded. As it happened this came about, but only after the patient had had an alarming rise of temperature extending over ten days. On the twelfth day a sloughing tumour of the size of a hen's egg came away and the patient got on all right. I should now deal with such a case by the abdominal route. In one case about two years ago a patient, 65 years of age, had a sloughing fibroid of the size of a fist, presenting at the os externum; there was a foul purulent discharge. The vagina was very narrow, from atrophy, and I had to face the problem whether to attempt a difficult vaginal myomectomy or to attack the tumour through the abdomen and run the risk of a septic peritonitis following. I decided on the former course. After dividing the cervix freely I attempted to cut up the tumour; but it was calcified and as hard as stone and I could make no impression on it. After an hour's hard work I managed to free it from its capsule; to deliver it I had to divide the posterior vaginal wall all the way down. The operation was completed by sewing up the vagina and cervix. This is the specimen shown in Fig. 1.

The abdominal route is the one required for the majority of cases. Here we have the choice of two procedures, the one conservative myomectomy, and the other radical hysterectomy. By myomectomy we mean the removal of a tumour from the uterus, leaving the uterus behind. It takes three forms, according to the position of the tumour. Subperitoneal myomectomy is the removal of a subperitoneal tumour; the uterus itself is left practically undisturbed. This plan was adopted in 11 cases, in three of which the appendages of one side were also removed. Interstitial myomectomy, or myomectomy by enucleation, is the removal of a fibroid from the substance of the uterine wall. An incision is made over the tumour, this is shelled out, and the incision is closed by sutures. 13 cases were treated in this fashion and in 11 of them a ventrofixation was done at the same time. Submucous myomectomy, or hysterotomy, means that the uterus is deliberately opened, as in a case of Caesarean section; a tumour (instead of a baby) is removed from its cavity and the uterine incision is sewn up again. This plan was adopted in Cases 11, 32, and 106. Abdominal myomectomy is an ideal conservative procedure but it is not always applicable. It was employed in 27 cases in this series. It is chiefly adapted to solitary fibroids or to cases in which not more than two or three tumours are present. It is of little advantage in patients who are past the child-bearing age, and it is contra-indicated when an apparently single subperitoneal fibroid is associated with profuse hæmorrhage, because in such a case there is almost certainly a submucous fibroid present in addition. When the uterus is uniformly enlarged by a rounded tumour it is justifiable to split open the uterus and remove the tumour from the interior. Hysterectomy is the plan to be followed in cases where myomectomy is unsuitable, and especially in all cases of multiple fibroids and in cases of cervix fibroid. When both appendages are diseased and require to be removed, it is always better to remove the uterus than to do a myomectomy. Hysterectomy is of two kinds: in one case the greater part of the cervix is left behind; this is known as supravaginal hysterectomy or subtotal hysterectomy. In my list of cases this operation is always understood when "abdominal hysterectomy" is spoken of. In most cases I regard this as the best procedure, and this view is shared by many

(To be continued.)

TWO CASES OF INTESTINAL OBSTRUCTION IN CHILDREN.

By E. P. BAUMANN, M.D. EDIN., M.R.C.P. LOND.

CASE 1. Acute intussusception reduced by manipulation.—My first case was that of a little girl, aged nine years, the daughter of a relative, to whom I was urgently summoned on the evening of Sept. 17th, 1906. It appears that the child, who was convalescent from a recent attack of whooping-cough and in fair general health, had come home from school that afternoon complaining of "stomach-ache," the result, she said, of a fall whilst playing some game. As she complained of very severe pain and seemed ill she was put to bed and various domestic remedies were applied both internally and externally—amongst others, a dose of Gregory's powder was administered. Nothing served, however, to allay the condition and the child lay moaning and writhing in pain. She seemed after nightfall to become very collapsed and on measuring her temperature and finding that the thermometer registered less than 97° F. the parents became alarmed and sent for me in haste. On my arrival I found the patient in a state of collapse, with a pale face, sunken eyes, and a rapid and compressible pulse. She lay with her knees drawn up and complained of severe pain in the lower abdomen. The tongue was dry and furred. The temperature was subnormal. I ascertained, on inquiry, that there had been no movement of the bowels that day, nor had there been any vomiting. On palpation of the abdomen there was readily felt a tumour lying transversely immediately below the level of the umbilicus. The mass was cylindrical and sausage-shaped, distinctly curved, smooth, and of firm elastic consistence. Per rectum the rounded end of the tumour was

distinctly felt, forced down against the finger when the patient strained and receding when the abdominal muscles relaxed. The finger on being withdrawn from the rectum was found to be coated with blood-stained mucus. I informed the parents that an intussusception existed and urged upon them the necessity for immediate operative interference. Before taking steps to secure surgical assistance I determined, however, to assay abdominal taxis. This method, a strong plea on behalf of which was advanced by Mr. Jonathan Hutchinson in the early "nineties," consists in kneading and manipulation of the abdomen and so attempting to reduce an intussusception. Ever since first I had read of this method I had been struck by its obvious value, but I had never before had an opportunity of putting it into practice. All the cases of intussusception I had previously met with were of longer duration, more or less firm adhesions having already formed. In the present instance the condition was probably of not more than at the most three or four hours' duration, and the case was consequently a very suitable one for taxis. I was able fairly well to grasp the tumour externally with the left hand and with the tip of the right forefinger in the rectum exerted a kind of bimammary manipulation, alternately increasing and relaxing the pressure with either hand. The tumour gradually disappeared with gurgling and borborygmus, and the child professed herself instantly relieved. I then ordered an enema to be administered, with the result that a copious motion was brought away. The abdomen was now quite flaccid and no further serious pain was complained of. After ordering a small dose of morphine I left the patient for the night. Three or four motions containing blood-stained mucus were subsequently passed and the child vomited once or twice. By the following morning the patient had completely recovered her normal health. For several days I anxiously awaited the trend of events, for the possibility of a recurrence was by no means excluded. There has been, however, no recrudescence of the symptoms, and it must be concluded that the manipulative measures were completely successful.

Remarks.—Unfortunately every case of intussusception is not so amenable to treatment as this one proved to be. In the majority of cases by the time the diagnosis is made adhesions have already formed and the necessary manipulations are then, on the one hand, little likely to be successful; and, on the other, not unattended by danger from the possibility of rupture of the gut with subsequent fatal peritonitis. In reference to the causation of the lesion in this case there were two factors of speculative interest, namely—(1) the convalescence from a recent attack of whooping-cough; and (2) the history of an injury to the abdomen. The former factor not infrequently figures in the history of cases of intussusception in children, whilst isolated cases have been recorded where abdominal trauma appeared undoubtedly to be the cause of the condition. In the present case both factors may have been of influence, the one in predisposing to and the other in determining the onset of the lesion.

CASE 2. Subacute intussusception simulating dysentery.—The second case was that of a female child, aged 15 months, whom I saw in consultation with Mr. W. Eddowes at Norwood, an outlying suburb of Johannesburg, on the night of Nov. 5th, 1906. The child had been ill for 72 hours with diarrhoea, the stools being loose and containing mucus and a considerable quantity of blood. A diagnosis of dysentery had been made and treatment administered in this direction without diminishing either the frequency or the unhealthy character of the motions. The temperature had at no time risen above the normal and tended rather to be subnormal. I was struck at the outset by the large amount of blood contained in the stools; the napkins looked like handkerchiefs used for a bleeding nose. With so much hæmorrhage considerable ulceration of the bowel must exist, and if there were much ulceration one would expect pyrexia at least at some stage of the illness. The stools varied in character, from a green and unhealthy to a yellow and natural colour, in the various discharges shown to me, and all contained blood and mucus. On inspection the child appeared to be fairly comfortable in spite of the frequency of the motions and she appeared to be in pain only at intervals when the legs were drawn up and there was evident intestinal colic. On examination the abdomen was found to be flaccid; in the left iliac region there was felt a small mass, about one and a half inches long and a finger's breadth in diameter. This mass, which was distinctly tender to palpation, by no means corresponded to the typical sausage-shaped tumour described in the preceding case; its presence very strongly suggested an

right base. There was a well-marked eruption, chiefly on the shoulders, chest, and back, but extending also to the abdomen, arms, and legs. It consisted of purpuric patches, the larger about a quarter of an inch in diameter, and small petechiae resembling flea-bites. Kernig's sign and *tache cérébrale* were present but not to a marked degree, and there were no retraction of the head or muscular rigidity, and no strabismus or nystagmus. The pupils were equal and somewhat dilated and reacted sluggishly to light. His face was flushed and his appearance resembled that of a pneumonia patient, the movements of the *alae nasi* being well marked. The urine was of specific gravity 1034, with a slight trace of blood and albumin. In the evening he had delirium of a muttering type and was unable to answer questions. During the night he had a slight fit. On Feb. 15th the patient was worse. He was unconscious and the breathing was more laboured. The temperature was 101.2°, the respirations were 50, and the pulse was 110. The right side of the face was now paralysed and the right arm and leg were flaccid and motionless. The left limbs were in constant movement, the left hand picking at the bedclothes, and the fingers presenting movement of athetosis. There was no cardiac murmur. A few rhonchi were heard at the base of the right lung, but there was no evidence of pneumonia. There were no ocular symptoms and no head retraction or rigidity of muscles. The patient became worse and died at 6.30 on the morning of Feb. 16th. A specimen of the cerebro-spinal fluid withdrawn by lumbar puncture was found to contain large numbers of the diplococcus pneumoniae of Fraenkel. Weichselbaum's diplococcus intracellularis was absent.

A necropsy was made on Feb. 17th. On opening the skull a considerable quantity of thick purulent fluid was found over the vertex in the pia-arachnoid space, most marked over the left hemisphere and affecting chiefly the occipital and frontal convolutions. At the base the nerves were found to be matted together. The dorsal surface of the cerebellum was thickly coated with the exudate which extended over the pons into the orbital region and into the fissures of Sylvius and Rolando. The mesial surface of the brain was also involved. Both lateral ventricles were dilated with excess of fluid. The basal nuclei were healthy. There was no sign of hæmorrhage. In the left lung a few small areas of consolidation were found in the upper part of the lower lobe, but there was no hepatization. The bronchial glands at the root of the left lung were caseous. The right lung was normal. The heart muscle was flabby but the valves were normal. The liver and kidneys were congested but otherwise normal. The spleen was enlarged and diffident.

The chief points of interest in this case appear to be (1) the presence of a well-marked purpuric rash in cerebro-spinal meningitis of pneumococcal origin; and (2) the absence of such characteristic symptoms of cerebro-spinal meningitis as head retraction, muscular rigidity, strabismus, and nystagmus. The case also emphasises the importance of a bacteriological examination of the cerebro-spinal fluid in cases of this kind.

Hampstead, N.W.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

NOTES ON TWO CASES: RUPTURE OF THE AORTA AND RUPTURE OF THE LEFT VENTRICLE.

BY REGINALD A. FORSTER, M.B., CH.B. ABERD.,
ASSISTANT PHYSICIAN, ROYAL ASYLUM, ABERDEEN.

The first case was that of a female patient, aged 79 years. She was slightly demented and for several years had led a quiet, regular life. She had been confined to bed for three weeks prior to her death, suffering from bronchitis with pyrexia, but had been convalescent for four days when she died suddenly on the fifth morning. At 10.5 A.M. on that day, while lying in bed, she all at once became very pale and died immediately.

The post-mortem examination revealed the following conditions. Both lungs were markedly emphysematous; the pericardial sac was found to be distended with about four fluid

ounces of serum and a firm blood clot, weighing nine ounces, which encased the heart. The heart was large and the aorta somewhat dilated. On opening the aorta a large rent was seen in the lower and posterior walls of the arch, measuring three inches in length and extending round three-quarters of the circumference of the vessel. The blood had evidently broken through the inner and middle coats of the aorta, dissected its way down in the tissues between the aorta and pulmonary artery, and finally at the origin of the latter vessel from the heart had burst into the pericardial sac. The walls of the aorta were thinned and showed some small atheromatous patches, though there were no marked signs of degenerative changes. The valves of the heart were healthy and competent.

The second case was that of a male, aged 57 years, who was also slightly demented and had not done any physical labour for two years. For the past nine months he had been in failing health; his arteries were very atheromatous and his general appearance was that of premature senility. He complained of a general feeling of weakness but had no pains of an anginal nature. The night before his death he went to bed apparently in his ordinary health. The next morning, while still in bed, he suddenly became very pale, gave two inspirations of a gasping character, and died.

At the post-mortem examination the left lung was found to be collapsed completely, evidently an old-standing condition, and occupied only a very small space in the upper part of that side of the chest, to the wall of which it was firmly adherent. The right lung was slightly emphysematous. The pericardial sac contained about six fluid ounces of serum and five and a half ounces of soft blood clot. A rupture, measuring half an inch in length was present in the anterior wall of the left ventricle, close to the intraventricular septum and midway between the apex and base of the ventricle. The edges of the rupture were ragged and the hole through the ventricular wall was cone-shaped, the base of the cone being the external opening. The heart muscle was flabby, but there was no naked-eye appearance of fatty degeneration. The aorta was atheromatous and numerous calcified plates were seen in its walls. The descending branch of the left coronary artery was almost completely occluded at its origin by atheromatous degeneration of its walls, and at this point the vessel was of a stone-like hardness. This branch was traced down to the site of rupture and evidently the myocardium, deprived of its blood-supply by the atheromatous obstruction, had undergone the necrosis spoken of by Ziegler as myomalacia cordis. The wall of the ventricle thus weakened by the necrosis had given way. The fact that the retracted left lung gave no support to the heart on that side may also have been a factor in the resulting rupture. Both these patients had been inmates of the Royal Aberdeen Asylum for some years.

I am indebted to Dr. J. Reid for his permission to publish these cases, and I have to thank Dr. Duncan of the pathological department at the University of Aberdeen for his kind assistance in the preparing of the specimens.

Aberdeen.

NOTE ON A CASE OF STREPTOCOCCUS WOUND OF THE FINGER.

By W. P. COWES, M.D.,

SURGEON TO THE BOSTON DISPENSARY; FORMERLY SURGEON TO THE ACCIDENT WARD, MASSACHUSETTS GENERAL HOSPITAL.

THIS case is reported as the unusually short period of incubation is of interest.

The patient, who was a married man, 44 years of age, was seen in the accident ward of the Massachusetts General Hospital on Oct. 28th, 1905. The history was as follows. About 6.30 A.M. on that day he was sparring with a fellow workman and in delivering one of his blows he struck the back of the index finger of his right hand against his opponent's tooth, making an incised wound. He was seen at the accident ward before 12 noon that day. Examination showed a wound on the index finger just posterior to the first knuckle; this was seared over. There was no other wound found nor were there evidences of any septic places around the hand. On opening the wound pus was seen. A cover-glass preparation was made and a culture was taken. The wound was douched, very slightly enlarged, touched with carbolic acid and alcohol, and drained. The finger did well and the man

intussusception, but I had to confess that it might have been occasioned by an enlarged and inflamed gland, or even by a faecal accretion. Rectal examination proved negative. I expressed my suspicions but did not meet with much credence, the more so as another member of the family, a boy, aged three years, had also that night passed a blood-stained motion. Now, the firmest adherent to the doctrine of the necessity for suspecting the existence of an intussusception in every unexplained abdominal derangement cannot conscientiously assert that this lesion occurs in an epidemic form in families. I was reluctantly compelled, therefore, tentatively to acquiesce in a diagnosis of dysentery. This I did the more readily in view of the fact that the treatment adopted—frequent doses of sodium sulphate by the mouth, together with high rectal injections of astringent solutions—was not directly inimical to either condition. Two days later, on Nov. 7th, I again saw the patient with Mr. Eddowes. No change had yet occurred in the frequency and character of the motions but the child was distinctly losing ground. There was no vomiting now or at any other stage of the illness. On abdominal examination I was unable to discover the mass which had been present at my first visit, but Mr. Eddowes informed me that he had distinctly detected it a few hours before my arrival. Now this alternating presence and absence of the tumour, accompanied by frequent bloody and mucous stools of an otherwise not decidedly unhealthy texture, is so characteristic of the condition that I with more firmness declared that in my opinion the case was one of subacute incomplete intussusception for which an immediate exploratory incision was indicated. Once more my dictum was rudely shaken by the discovery that the elder child, before mentioned, had also that morning voided a blood-stained motion. On the previous occasion his stool had been pale, loose, and distinctly blood-stained, leading one to fear that he might be at the beginning of an attack of dysentery; this time the motion was healthy and well-formed, containing only a streak of blood such as is not uncommonly produced in children by a rectal polypus. I performed a rectal examination with a view to discovering a growth of this character but the result was negative. I next suggested that the original patient, the baby, should be examined in a similar quest. A whiff of chloroform was consequently administered and a careful rectal examination undertaken, both digitally and by inspection through a speculum; the result was *nil*. Abdominal palpation also proved negative. On Nov. 9th Mr. Eddowes telephoned to me to the effect that the child was slowly sinking. On ascertaining that the elder boy was perfectly well and had passed no further blood in his stools I once more declared my views as to the existence of an incomplete intussusception. This time I decisively asserted my opinion, insisting that in immediate operative interference lay the only possible hope of saving the life of the patient.

On the following morning, the ninth day of the illness, Dr. G. A. E. Murray of Johannesburg was summoned to perform a laparotomy, which I witnessed. On opening the abdomen in the middle line coils of distended small intestine at once protruded. On tracing the gut downwards it was found to grow narrowed and its walls were seen to be discoloured, the congestion becoming more intense until, about the upper third of the ileum, a very small enteric involution was met with. The intussusception was readily reducible and the mesentery at this point was then anchored by a stitch or two to the peritoneum of the anterior abdominal wall. The whole operation occupied not more than some 20 minutes, the greatest haste being necessary in view of the extremely collapsed condition of the patient. Hot bottles, stimulants, and subcutaneous injections of normal saline solution were energetically employed, but without avail, for the child never rallied and death supervened two hours later.

Remarks.—This case appears to me to present many features of unusual interest which seem to render it worthy of the detailed description I have given of its course. In the first place, there is the fact of the comparative rarity of these cases of incomplete intussusception in which the occlusion of the bowel is incomplete and the passage of faeces continues unimpeded, whilst there is little or no vomiting. These cases may last for weeks or become chronic and exist for months or years, death in most instances being due to exhaustion. Secondly, there was the considerable amount of hæmorrhage from the bowel. Usually, in subacute or chronic intussusception the catarrhal changes at the neck of

the involution are comparatively slight and the stools are characterised only by small hæmorrhages. Thirdly, there was the similarity to a case of dysentery—superficial, it is true, yet sufficiently exact to obscure the diagnosis. In a paper on chronic intussusception published in the *Transvaal Medical Journal* of November, 1905, I drew attention to the frequency with which diagnostic difficulties of this character arise. Fourthly, there were the disappearance and reappearance at intervals of the abdominal tumour. According to Treves, a tumour is felt on abdominal examination in only 50 per cent. and rectally in only 32 per cent. of these cases, and in the paper already quoted I have drawn attention to the recognised fact that the tumour, once it has been felt, may disappear from time to time. For this reason it is essential that the examination of the abdomen should be undertaken both thoroughly and repeatedly. Fifthly, the fact that another child of the same family should also, and at about the same time, have passed blood-stained motions was perhaps the most perplexing factor of this difficult case. Had it not been for this fact I should have insisted upon operative interference on the occasion of my very first visit, when the patient was still of comparatively good health and the prospects were favourable. In the circumstances we had to await developments in the second child and in the meanwhile lost valuable time. Mr. Eddowes has since informed me that a few days after the death of the patient a native servant of the same household had developed undoubted dysentery, for which he was successfully treated at the Johannesburg Hospital. The question thus arises as to whether it is possible that both children had also suffered from dysentery, the baby developing her intussusception as a sequela to this disease. If so, one would expect the elder child to have been constitutionally affected, whilst apart from his blood-stained motions he appeared throughout to be in perfect health. The parents themselves attached little importance to his condition and the mother informed me that all her children from infancy had been known occasionally to pass blood in their stools whilst enjoying perfect health. Lastly, the fact of the situation of the intussusception in the course of the ileum is of interest, the enteric being one of the rare forms of intussusception.

Johannesburg.

A CASE OF PNEUMOCOCCAL CEREBRO-SPINAL MENINGITIS SIMULATING "SPOTTED FEVER."

By AUGUSTUS H. COOK, M.B. LOND.,
SENIOR SURGEON, HAMPSTEAD GENERAL HOSPITAL;
AND
G. F. MCLEARY, M.D., D.P.H. CANTAB.,
MEDICAL OFFICER OF HEALTH OF HAMPSTEAD.

The following case appears to be of especial interest at the present time in view of the prevalence of epidemic cerebro-spinal meningitis in various parts of the United Kingdom. The patient, a man, aged 24 years, was an architect's assistant and had been working in the vicinity of Hampstead for some months. He was a well-built young fellow of considerable prowess as an athlete. His previous health had been good, but there was a history of a slight attack of influenza about a month ago, and he is said to have had a severe attack of "sunstroke" (fever, severe headache, and vomiting) about eight years ago, when he was in bed a week. The patient's mother's brother is said to have died from meningitis some years ago after an illness of 36 hours.

The patient's illness began on Feb. 12th, when he returned from work in the evening complaining of headache and motions. He vomited three times during the night. On the next day he got up for a few hours; he was "dull and heavy" but did not sleep. The temperature was 100.2° F. He took a dose of cascara and had several loose motions. During the night he apparently had a fit. On the 14th he was seen for the first time by us. In the morning the temperature was 100°, the pulse was 108, the respirations were 48, the tongue was dry and coated with brown fur, and the throat and pharynx were dry and glazed; there was no enlargement or ulceration of the tonsils. He was in a semi-comatose condition and could only with difficulty be roused. The heart and lungs were normal except that there were some dry rhonchi at the

on pulmonary tuberculosis. He had treated some 20 by tuberculin controlled by the opsonic index and he was convinced that in many cases it had achieved a great result.

Dr. Raw distinguished between two forms of abdominal tuberculosis: (1) a primary form due to the bovine type, and (2) a secondary form due to the human type. In many cases of pulmonary tuberculosis running an unfavourable course there was evidence of intestinal infection and he thought it difficult to accept the suggestion that this was due to a secondary infection by a bovine type.

Dr. J. P. LORD said the question raised was of great importance as regards public health. If milk was infected with tubercle it might be either the bovine or the human variety: if the bovine the cows could be tested and the source of infection traced; if the human variety it was a matter of difficulty to trace the infection. He asked by what means it was possible to distinguish between the bovine and human variety.

Dr. G. A. CRACE-CALVERT said that he did not think that the report of the commission altogether supported Dr. Raw's contention. It had been possible by the passage of the bacillus through calves to obtain a bovine type. The two types were not certainly different. The fact that T.R. tuberculin would act in all varieties of tuberculosis was a point in favour of the identity of the two types of the animal. In support of this view he quoted the following cases, the first a case of pulmonary tuberculosis which died after eight inoculations of T.R. tuberculin; the second, a case of tuberculous abdominal gland which recovered after four inoculations. In the report of the commission both human and bovine tubercle came from the renal glands, and there was no class of case which could be said to be definitely bovine or human.

Dr. HOWARD H. TOOTH asked what precautions were taken with regard to the injection, and whether the opsonic index had been taken.

Dr. F. M. SANDWITH said that in Egypt every form of tuberculosis mentioned in the paper was common except tuberculous meningitis. In Egypt surgical tuberculosis was most common. Tuberculin had been used with bad results. He did not think it rare for pulmonary tuberculosis to follow tuberculous glands. In Egypt the mothers often suckled their children for two years, and when cows' milk was given was nearly always boiled. Tubercle was extremely rare in cattle in Egypt and yet all forms of tuberculosis were common except tuberculous meningitis. This fact did not support the distinction of types of bacilli, but he thought that the investigation of the disease in Egypt might present some interesting results, for human tuberculosis was common, while bovine tuberculosis was rare.

The PRESIDENT also commented on the rarity of pulmonary tuberculosis in association with surgical tuberculosis.

Dr. RAW, in reply, said he did not think that T.R. tuberculin had any beneficial effect on pulmonary tuberculosis. He thought it was possible to distinguish between varieties of the tubercle bacilli by culture. Avian tubercle was quite distinct from bovine and human tubercle. He thought it of the greatest importance to eradicate tuberculous cattle from the herds which supplied milk to the large towns, for a single tuberculous cow might infect the whole of the milk coming from that herd.

MEDICAL SOCIETY OF LONDON.

Operations for Malignant Growths of the Naso-pharynx and Pharynx.—Hæmaturia due to Bilharzia Hamatobia causing Papillomata of the Bladder.

A MEETING of this society was held on Feb. 25th, Mr. C. W. MANSELL MOULIN, a Vice-President, being in the chair.

Mr. F. S. EVE read a paper on Some Operations for Malignant Growths of the Naso-pharynx and Pharynx. He first alluded to the complexity of the subject of operations in this region. It was often found that the superior maxilla had been sacrificed unnecessarily and the contour of the face and the patient's power of mastication impaired thereby. To meet many of these cases he had designed an osteoplastic operation which obviated the removal of the superior maxilla. By his procedure the superior maxilla was raised from its bed and bent upwards and forwards without removal. This gave a full view of the naso-pharyngeal cavity. Any growth present could then be removed and the

superior maxilla replaced. Several cases were referred to. The first time that the operation was performed by Mr. EVE was in October, 1904, but the patient died from shock. The next case was operated upon in February, 1906, with complete success, the patient being presented before the meeting and the tumour, a fibro-sarcoma, exhibited. Lately Mr. EVE had slightly modified his procedure, for which he claimed the following advantages: the avoidance of parotid fistula or interference with the lacrymal duct and the preservation of the superior maxilla. On the other hand, the risk of shock by interference with the structures at the base of the skull was considerable and the division of the lower fibres of the facial nerve was inevitable. The procedures of various surgeons were then described and discussed—namely, the methods of Watson Cheyne, Annandale, Langenbeck, Nélaton, Chabot and Guérin, and Kocher. Mr. EVE then referred to malignant disease of the tonsil and certain pharyngeal growths, most of which were best removed through the mouth. One of the chief causes of death in such cases was pneumonia; this was best prevented by a preliminary laryngotomy. Laryngotomy and tying the external carotid Mr. EVE regarded as necessary preliminaries in all operations for extensive pharyngeal tumours.—Mr. MANSELL MOULIN congratulated Mr. EVE on his paper and the success of the case shown. He (Mr. Mansell Moulin) had employed the operation described by Mr. EVE. The chief difficulty was the preservation of the soft palate and this could be done by removing the periosteum with its muscular attachments from the hard palate.—Dr. F. PARKES WEBER and Dr. F. J. PORTNOR discussed the prognosis of these cases and Mr. EVE replied that in many instances the tumour presented quite a low degree of malignancy. A case of lymphosarcoma, for instance, had remained well for many years.

Mr. H. J. CURTIS read a paper on a case of Hæmaturia due to Bilharzia Hamatobia causing Papillomata of the Bladder, which were removed by suprapubic cystotomy. The patient was a Matabele boy, aged about ten years, who had suffered for some months previously from pain over the bladder, frequency of micturition and incontinence, and hæmaturia. The urine was tinged with bright blood throughout, whereas usually in such cases the blood came only at the termination of micturition. The case occurred in Rhodesia, where infection by the bilharzia, except in people coming from outside, was practically unknown. The symptoms suggested the presence of stone or villous tumour. The presence of calculus was negatived by sounding and suprapubic cystotomy was performed and the growths, wherever possible, were excised and the nodular condition of the vesical mucous membrane was treated by daily irrigation through the wound with a solution of silver nitrate, increased gradually from half a grain to two grains to four ounces of distilled water. The patient was able to be up and about within a week or two of the operation. Only twice during a period of four months was a faint tinge of blood visible. The condition of the patient remained satisfactory and when heard of two years later there had been no obvious recurrence of symptoms. Microscopic examination of a papilloma revealed the presence of numerous ova of the bilharzia hamatobia in the substance of the growth. Such definite tumour formation as the result of irritation by an animal parasite was interesting in relation with the more complex question of the origin of cancer. Attention was also directed to the important observations of Captain S. R. Douglas, I.M.S., and Major F. W. Hardy, R.A.M.C.,¹ that of the cells found in the urinary deposit in 50 cases of soldiers suffering from bilharzia disease treated at Netley Hospital a very large proportion were found to be eosinophiles, and that in the presence of bilharzia the average percentage of eosinophiles in the circulating blood was increased to 16.4, and in one exceptional case to 40 per cent. (the normal being 4 or 5 per cent.). It was so also in disease produced by other parasitic worms, such as trichinosis, hydatid disease, and dracunculiasis (guinea-worm), a useful point to remember where the diagnosis was obscure. As a rule, the diagnosis was readily made by the presence at the end of micturition of blood teeming with ova having a characteristic spine at one end. The disease was practically unknown in Rhodesia, the present case being the third treated in Bulawayo Hospital according to the Reports for 1897-1906. All three cases—two whites and one native—

¹ THE LANCET, Oct. 10th, 1903, p. 1002.

was soon discharged. The cover-glass showed numbers of streptococci and the culture was a pure one of that organism. From the time of the injury to the time when the man was treated could not have been over four hours.

NORTH-EASTERN HOSPITAL FOR CHILDREN, HACKNEY-ROAD, E.

A CASE OF VOLVULUS OF THE SMALL INTESTINE IN A
CHILD, AGED SEVEN YEARS.

(Under the care of Mr. J. P. LOCKHART MUMMERY.)

FOR the notes of the case we are indebted to Dr. G. P. Norman, late house physician and acting resident medical officer.

The patient was a boy, aged seven years. He was sent to the North-Eastern Hospital for Children as a case of appendix abscess. The history was that for some time the child had had a bad cough but it had got slightly better recently. At 6 A.M. on the day before admission the child complained of severe pain in the abdomen. Two hours later he was sick and vomiting continued throughout the day at frequent intervals. There was no action of the bowels, though he had had a normal motion on the previous day. On the next day the pain continued and he vomited twice in the morning. The mother did not notice anything special about the vomit. He was seen by a medical man in the afternoon who sent him to the hospital at once.

On admission at 4 P.M. his face was flushed and he seemed in pain. His respirations were rapid and noisy. The pulse was very rapid and running. He did not vomit after admission. Râles and rhonchi were present in both lungs but there was no dulness. The lower part of the abdomen did not move with respiration and a swelling could be seen in the upper part of the right iliac fossa; the skin was not red over it. On palpation the swelling felt rounded and firm and was very tender. It was dull on percussion. Good resonance was obtained over the remainder of the abdomen. Per rectum nothing definite could be felt. There was no distension of the abdomen. The pulse-rate was 130, the respirations were 40, and the temperature was 99.8° F. The temperature was higher when taken at home. Everything seemed to support the diagnosis of appendix abscess and it was decided to operate. Mr. Mummery performed the operation under chloroform.

An oblique incision two inches long was made through the skin over the appendix area, the muscles were divided, and the peritoneum was opened. On opening the abdomen some blood-stained serum escaped and a black mass could be seen. The incision was enlarged and the mass was found to be a loop of intensely congested small intestine, close to the cœcum, which had been twisted on itself. It was extremely tense but still shiny. Gas slowly oozed from one pin-hole spot when the bowel was handled. As the twist could not be undone without bursting the bowel and its recovery was very doubtful it was decided to resect it. A pair of clamps was then put on the bowel at each end of the congested portion and the bowel was divided between the clamps and the affected portion removed, the peritoneum being ligatured in several portions. The ends of the divided bowel were united by means of a Murphy's button reinforced by a few sutures, this being the most rapid method possible. The incision through the peritoneum, muscles, and skin was then closed except at the lower end where a gauze drain fixed in a piece of india-rubber tubing was put down to the junction in the bowel. During the early part of the operation the condition of the patient was bad, but it improved later, though the pulse continued weak. Six ounces of normal saline solution were injected shortly after the operation, but the patient gradually grew weaker and died eight hours after the operation. On

examining the portion of bowel removed the volvulus was found to have occurred around a caseating gland in the mesentery. It was only with considerable difficulty that the bowel could be untwisted, even after it had been removed.

Remarks by Mr. MUMMERY.—Volvulus of the small intestine is a very rare condition and is said not to occur in normal bowel. In this case the caseous gland in the mesentery appeared to have been the point about which the twist occurred and the direct cause of it. The close resemblance of the condition to appendix abscess was remarkable and it seemed hardly possible to have made any other diagnosis. The classical symptoms of acute obstruction were not prominent. Vomiting was well marked during the first 24 hours but on the second day had almost ceased and at no time was there fecal vomiting. There was no distension of the abdomen at all and the swelling caused by the strangulated bowel was not resonant on percussion.

Medical Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Human and Bovine Tuberculosis; with Especial Reference to Treatment by Special Kinds of Tuberculin.

A MEETING of this society was held on Feb. 26th, Mr. J. WARRINGTON HAWARD, the President, being in the chair.

Dr. NATHAN RAW read a paper on Human and Bovine Tuberculosis. He said that tuberculous infections of the human body were divisible into two groups: (1) those caused by the bacillus *typus humanus*, and (2) those caused by the bacillus *typus bovinus*. These bacilli were varieties of the same species, but gave rise, according to the method of infection, to quite distinct and different lesions. The cultural differences between bacilli of human and bovine origin were sufficiently characteristic when typical to differentiate them, but the microscopical appearances of the bacilli were not characteristic. His conclusions were based on a clinical observation of over 4000 cases of phthisis pulmonalis, including over 700 careful post-mortem examinations on cases of tuberculosis, together with laboratory research and animal inoculation. Provisionally he classified the various tuberculous lesions in the human species into two great groups as follows. Group I.—Lesions caused by the tubercle bacillus, *typus humanus*. (a) Phthisis pulmonalis; (b) secondary ulceration of intestines; and (c) tuberculous laryngitis. Group II.—Lesions caused by the tubercle bacillus, *typus bovinus*, conveyed by milk, meat, &c., and also by direct infection. (a) Acute milky tuberculous; (b) primary intestinal and mesenteric disease, including (1) tabes mesenterica, (2) tuberculous peritonitis, and (3) tubercle of the pelvic organs; (c) tuberculous lymphatic glands; (d) tuberculous joints and bones; (e) lupus; (f) tuberculous meningitis; and (g) tuberculous ulceration of the cornea. The chief object of the paper was to produce evidence of an important character, as the result of the inoculation of animals, to show that tuberculous glands of the neck are of bovine origin, the result of absorption through the tonsils and mouth. Human and bovine tuberculosis were apparently antagonistic to each other and a mild attack of one seemed to confer immunity against the other. This had an important bearing on treatment. He had had a new tuberculin prepared based on these observations and results would be announced.

Dr. DAVID LAWSON said that he had been struck by the fact how seldom the so-called surgical forms of tuberculosis were present in cases of well-marked pulmonary tuberculosis. Out of some 700 cases of pulmonary tuberculosis in various stages of the disease he had only seen three cases with surgical tuberculosis. On the other hand, he had difficulty in accepting the suggestion that the difference in infection was due to a variation in the organism. Milary tuberculosis was said by Dr. Raw to be due to the bovine type, whilst pulmonary phthisis was due to the human type, and yet it was not uncommon to see pulmonary tuberculosis terminate in a milary tuberculosis, and tuberculosis terminate in a milary tuberculosis, and he could not think that the patient had become infected by another variety of the organism. Dr. Raw had stated that T.R. tuberculin did not exert a beneficial

been very fairly satisfactory; flexion and extension were quite good, abduction was fair, but rotation of the humerus on its own axis was poor. All these movements were improved by exercise and rubbing. It was pointed out that should the operation be performed again for a similar pathological condition it might be advisable to add a posterior incision to the anterior one and so possibly divide the neck of the scapula from behind, and also to remove a little more bone from the neck of the scapula than was done in this case.—Mr. SPENCER said it was difficult to define such a largely used term as excision. At the shoulder-joint the posterior incision had long been recommended; the circumflex nerve had, of course, to be avoided.—Mr. JOHNSON asked as to the nature of the passive movements used. He suspected that sometimes too vigorous early movement defeated its object by causing more cicatricial tissue to form.—Mr. KELLOCK, in reply to a question by Mr. C. GORDON WATSON, said that he sacrificed the upper part of the long head of the triceps as well as the long head of the biceps; these were less important than the muscles inserted into the upper end of the humerus because they had other attachments. As to the passive movements he agreed with Mr. JOHNSON. In the present case he had, for special reasons, begun them on the tenth day but as a rule he waited until later. He recognised that the operation he now proposed was rarely applicable to cases of disease, such as tuberculosis, for this usually affected the humerus more than the scapula.

PATHOLOGICAL SOCIETY OF LONDON.

The Parathyroid Glands in Man.—A Histological Study of the Human Parathyroid Glands.

A MEETING of this society was held on Feb. 19th, Dr. P. H. FRY-SMITH, the President, being in the chair.

Dr. DAVID FORSYTH read a paper founded on a detailed examination of the Parathyroid Glands in nearly 60 human bodies. After referring to the contradictory views held on the subject, some regarding the bodies as essential in the highest degree to life, and others looking on them as mere embryonic rests of thyroid tissue, he began by describing the naked-eye anatomy of the glands. Their number, though generally two to each lobe of the thyroid, was inconstant and might be three, four, five, or even six. Their position in the neck was variable, but they showed a predilection for certain sites and never lay superficial to the sternohyoid, sterno-thyroid, or omo-hyoid muscles, being invariably wrapped in the same compartment of the deep cervical fascia as the thyroid gland. They were to be sought either at the junction of the upper and middle thirds of the posterior border of the thyroid lobe or at the junction of the middle and lower thirds or around the posterior pole. Their relative numbers in these positions were 4 : 3 : 2. Other less common sites were the interior of the thyroid lobe, the connective tissue round the superior pole or hidden between the thyroid and the trachea. A parathyroid was found in the anterior mediastinum of the thorax. The frequent absence of distinguishing features was probably the cause of their being sometimes overlooked and the risk of omission was further increased feeling that parathyroid tissue might be associated with lymphatic glands, thymic residues, or accessory thyroids, without arousing suspicion as to the composite nature of the whole. The typical parathyroid was an elongated, ovoid, slightly flattened body of a pale-pink hue with a smooth, glistening surface on which ramified a few branching vessels. It very frequently contained much fat and might present few features except those of a nodule of well-vascularised adipose tissue. This variety would be specially liable to escape recognition. Some specimens were brown in colour like accessory thyroids, while rarely a parathyroid black in tint might be found. The size varied from 2.5 centimetres by 0.5 centimetre and there was no constancy in the total volume of parathyroid tissue in different subjects, one individual having, perhaps, 10 or 23 times as much parathyroid tissue as the next examined. A point of importance in connection with the supposed embryonic character of the glands was the relation between parathyroids and accessory thyroids. It was clear that if isolated parathyroids became thyroidal their number would show a decrease with age, while accessory thyroids should increase and be found in the position occupied by parathyroids. Statistical evidence was adduced showing

that parathyroids were most numerous in the first year of life, thereafter progressively decreasing till old age. Within the former period they occurred to the number of three to six; between the first and tenth years the greatest numbers were three and four; above ten years two was the maximum. On the other hand, accessory thyroids were not found in 75 per cent. of the infants under one year, in 43 per cent. of the children between one and ten years, and in 5 per cent. of the adults. These figures showed that up to one year of age parathyroids were 7.2 times as common as accessory thyroids, from the first to the fifth years 3.5 times, from the sixth to the tenth years 1.4 times, while between the eleventh and twentieth years equality was established. Thereafter the preponderance went to the accessory thyroids. Next the histology of the organs was considered in detail, the new facts brought forward by Dr. Forsyth being illustrated by microscopical specimens and lantern slides. While to some extent confirming the classic work of Sandström the present research showed that far from being embryonic and functionless the parathyroids normally secrete colloid material. Welsh's supposition that the organ contained two varieties of cells—the oxyphile and the principal—was quoted and it was shown that these were in reality two stages in the activity of one kind of cell. The principal cell was the exhausted cell and the oxyphile the rested cell. The protoplasm of the former gradually re-filled with eosinophile granules which were extruded into the surrounding lymphatic spaces and passed into the lymphatics either directly or after aggregating to form drops of colloid among the cells. Often the polyhedral parathyroid cells grouped themselves round a central lumen containing colloid and a definitely formed vesicle thus resulted. Photographs of all stages from the massed arrangement of the cells to a regularly formed vesicle were thrown on the screen and the resemblance of the last to the thyroid was noted. As a rule, any one section of a parathyroid showed cells in all stages of activity and rest and the changes in the cells during secretion were the same as those in the glandular epithelium of other organs. The secreted material agreed in its physical properties and micro-chemical reactions with that of thyroid colloid and the two appeared identical. Attention was drawn to the fact that for some little time after birth the parathyroid presented an immature appearance in contrast to that attained at a slightly later period. The infantile parathyroid had a uniform aspect of inactivity, the protoplasm of the embryonic cells being comparatively large in amount, but containing no oxyphile granules. Finally, mention was made of the pituitary gland which possessed clear cells and granule cells. In the course of this research many pituitaries, both of men and of animals, were examined and it would appear that the two varieties of its cells stood in the same relation to each other as the principal and oxyphile cells of the parathyroid. Cells intermediate in degree of activity between these two were found, as also were intercellular granular material, drops of secretion, and small vesicles.

Mr. W. L. HARNETT read a paper on a *Histological Study of the Human Parathyroid Glands*. After briefly summarising the work of the past 20 years on the parathyroid he gave a general account of the histology of the gland. The two types of cell ordinarily met with were described, the granular oxyphile cell and the clear principal cell; it was stated that transitional stages between these two were of common occurrence and the view was advanced that all were merely phases of the same cell, the oxyphile cell being the resting stage and the principal cell the discharged stage. The frequent occurrence of colloid in the gland was remarked upon and it was pointed out that the presence of colloid was associated with other evidence of activity in the presence of large numbers of oxyphile cells. Fat was found to be normally present in the gland when it showed signs of activity and it was stated that the gland which contained the most fat presented also the largest number of oxyphile cells and the greatest amount of colloid. After describing the appearances of the gland at various periods of life, he said that the conclusion to be drawn was that it began to show signs of activity in early childhood and became steadily more active as age advanced. No constant change was found in respect of which the glands differed from the normal glands at about the same period of life. In a case of parenchymatous goitre, however, in a girl, aged 18 years, the glands contained a considerable amount of colloid and presented a picture of activity quite unusual at

probably became infected from outside Rhodesia, the disease being endemic along the east coast of South Africa, in Natal, the Transvaal, and the Cape, and notably in Egypt. According to Captain Douglas and Major Hardy, the endemic area of the disease in Africa had been widely extended by the movements of infected soldiers, and the possibility of extension of the disease to other countries needed therefore to be borne in mind. Mr. Curtis also considered the mode by which infection occurred, the prognosis, and the means of treatment. One of the papillomata and microscopic sections were exhibited.—Mr. MANSELL MOULLIN remarked that bilharzia was certainly becoming more common than formerly, judging by his experience at the London Hospital. He had found urotropin a remedy of value.—Dr. F. M. SANDWITH recalled the fact that it was 40 years ago since the late Dr. John Hardy first directed attention to the subject of bilharzia. Dr. Sandwith had made search in the Egyptian papyri and it seemed probable that this disease was not referred to. In the present day there had been at least 100 soldiers discharged from the British army for the disease. Two cases had been recorded in persons who had never been out of the British isles, one by Mr. Berkeley Hill and one by Major E. C. Freeman, R.A.M.C. If it could spread in this way to one person it might do so to others. The parasite might, it was true, enter the body by the stomach but it could not live in an acid solution; probably it entered by the skin. The presence of eosinophiles was not a diagnostic feature as it occurred in various other diseases. He had tried urotropin. Undoubtedly it turned a septic cystitis into an ordinary cystitis but did not diminish the number of ova in the urine. No certain remedy had yet been discovered but the filix mas was the best. Some cases were cured by surgical measures. Papillomata occurred late in the disease. The disease produced many hundred deaths in Egypt and there must also be a very great number of cases in South Africa.—Mr. EYE referred to some specimens sent to the Hunterian museum some years ago by Mr. Herbert Milton of Cairo.—Mr. CURTIS replied.

CLINICAL SOCIETY OF LONDON.

Spinal Meningocele treated by Operation after Rupture.—Resection of the Jejunum and Colon for Carcinoma.—A New Method of Excision of Joints.

A MEETING of this society was held on Feb. 22nd, Dr. W. HALE WHITE, a Vice-President, being in the chair.

Mr. RAYMOND JOHNSON and Mr. O. E. REYNOLDS described a case in which a Meningocele in the Sacral Region was successfully treated by operation in an adult after the sac had ruptured spontaneously. The patient was a woman, aged 22 years, in whom the tumour of the back had only been noticed for about two years. The tumour was of the size of a large orange, and after spontaneous rupture of the thin skin covering its summit large quantities of cerebro-spinal fluid continued to escape. An operation was performed and the small opening by which the sac of the meningocele communicated with the theca was treated like the neck of a hernial sac and ligatured, the rest of the sac being removed. On the sixth day after the operation cerebro-spinal fluid again began to escape from a small opening in the otherwise healed wound. For 37 days the free discharge continued. A second operation was then undertaken and a very small opening which led into the theca was closed by suture. From this date no further leakage occurred and the wound remained soundly healed. Several months later the woman was reported to be in perfect health. A point of interest in this case was that the tumour formed by the spinal meningocele was not noticeable until adult life had been reached, although a small dimple in the skin over the coccyx had been present from birth. It was further of interest that during the period of more than a month, when cerebro-spinal fluid was constantly escaping in large quantities, the patient presented no symptoms directly attributable to the loss.—Dr. HALE WHITE referred to Dr. St. Clair Thomson's case in which large quantities of cerebro-spinal fluid dripped from the nose. The patient lost three times as much fluid that way as by the kidneys and yet was in perfect health.—Mr. W. G. SPENCER said that he had operated on a similar case which was leaking and suppurating at the time. There was a dermoid cyst in the wall of the meningocele and this was probably the source of the irritation that had

promoted rapid growth. In the present case the amount of fluid might have been due to local sepsis and so caused general symptoms, because it was derived merely from local area. He detailed two operations which he had performed in infants suffering from a like condition.—Mr. C. F. FAGGE said that with a view to the prevention of leakage he was in the habit of first suturing the dura mater transversely then dissecting up elliptical flaps from the deep fascia of the erector spinae, and suturing this longitudinally over the dura mater.—Mr. JOHNSON, in reply to Dr. ALEXANDER MORISON, said that no changes in the pulse-rate had been noted as the result of the loss of fluid. Indeed, the only change noted was relief of the headache. He disagreed from Mr. Spencer's explanation of the source of the fluid in the present case because cultures were sterile till quite late, and then the appearance of staphylococcus albus did not coincide with any increase in the amount of fluid poured out.

Mr. FAGGE communicated a case of Resection of the Jejunum and Colon for Carcinoma. The patient, a woman, aged 33 years, was admitted to Guy's Hospital with history of attacks of abdominal pain, relieved by vomiting extending over three months; the vomiting had been most severe for the past three weeks. A hard lump was felt in the right iliac fossa. To the left of this was seen a peristaltic wave in a large coil passing from left to right. The temperature was 96° F. and the pulse was 118. The abdomen was opened on the day of admission, Dec. 11th, 1905. A malignant mass was found in the jejunum 18 inches from the duodenum, involving also the hepatic flexure of the colon. The jejunum and colon were resected and closed, and double lateral anastomosis of jejunum to jejunum and ascending transverse colon was effected with small and large Murphy buttons, the former being passed about six weeks, and the latter four weeks, after operation. Microscopically the growth was a carcinoma.—Dr. HALE WHITE commented on the result of the case recorded. He shortly described a case occurring in a man aged 32 years. Duodenal ulcer had been diagnosed but at the operation a jejunal growth was found and short circuited. The patient died later with secondary deposits.—Mr. T. H. KELLOCK inquired whether any symptoms of stricture had appeared as the result of the use of Murphy buttons. He agreed as to the difficulty of deciding in this matter of the treatment of such cases, as the surgeon was practically deprived of the two-stage method of procedure.—Mr. FAGGE said that no symptoms at all were present in January of this year. As a general rule he thought that the use of Murphy's button was not good surgery, but it certainly saved time in many cases.

Mr. KELLOCK read a paper entitled "Excision of Joints, New Method of Operating at the Shoulder." Attention was first drawn to the fact that comparatively little change had taken place in the technique of the operation on the various joints. Comparison was made between the operation of excision as performed at the hip and at the shoulder: in the former the section of bone was made within the capsule, and no muscular attachments to the femur were disturbed, whereas at the shoulder the humerus was divided through the surgical neck and the insertions of the important muscles into the tuberosities were sacrificed as well as, in the case of a child, the most important seat of growth of the humerus. The operation now described was an endeavour to save the muscles and the epiphyseal line, whilst still preserving a moveable joint; it was carried out by removing the necessary amount of bone from the scapular instead of the humeral side of the joint. The operation as performed on the dead body was comparatively easy. After opening the joint by a long anterior incision the muscles attached to the upper end of the humerus were retracted; the coracoid process was broken but not completely separated and turned a little downward with the origins of the biceps and coraco-brachialis muscle. The neck of the scapula was then sawn through and the glenoid cavity completely removed, sacrificing only the long tendon of the biceps and a part of the middle head of the biceps and structures of comparatively little importance. The patient on whom the operation had been performed was a man, aged 41 years, who had sustained a dislocation of the left shoulder, complicated by fracture of the surgical neck of the humerus 11 weeks previously. The fracture had united firmly in good position, but the subcoracoid dislocation remained undisturbed. At the operation the glenoid cavity and part of the neck of the scapula were removed by gouge forceps and the head of the humerus fell back easily into the cavity. Passive movements were commenced early. The result has

sites. The compensation for public-house property constituted a heavy item in the outlay. These premises, however, were not spared, as the council was well alive to the immense injury done by drunkenness in the city. Apart from the action of the corporation in removing slums, commercial enterprise had been active; railway companies, warehouse companies, and so forth had swept away large numbers of insanitary dwellings. In 1883 some 16,000 insanitary dwellings existed. These had now been reduced to between 6000 and 7000, and the corporation had recently decided, pending the sanction of the Local Government Board, to deal with six more areas under the Housing of the Working Classes Act, and to erect suitable dwellings upon them. These schemes were estimated to cost £270,000. The paper was illustrated by a number of slides showing the old and the new buildings, and the various points in connexion with these latter.—Dr. S. R. ROSS exhibited a number of lantern slides, illustrating the life of the slum children, made from photographs taken in the course of his work as medical officer to the Society for the Prevention of Cruelty to Children.—Dr. G. G. STOFFORD TAYLOR said that the demolition of public-house property would not stem the tide of drunkenness. Education, regular employment, and public opinion could alone effect a reformation in the habits of the drunkard, and when these failed his children should be taken from him and brought up at the expense of the State in order to protect them from their vicious surroundings.—Dr. W. CARTER thought that the solution of the slum problem would largely depend upon the solution of the drink problem. Every successive medical officer of health of Liverpool had complained that their efforts at improved sanitation in the houses of the poor were rendered largely nugatory by the prevalence of intoxication. Years ago when the late Professor Parker and the late Professor Sanderson were invited by the corporation to inquire into the causes of the insanitary condition of Liverpool they gave a conspicuous place in their report to drunkenness among the working classes. The facts stated by Dr. Hope that £5000 a year were taken at three public-houses in one of the lowest districts of the city, and that in the whole city from one and a half to two millions sterling were spent yearly in intoxicating liquors were alarming. It was a good thing for Liverpool that its great public officers were not merely hard routine officials but had the enthusiasm of humanity to aid them in their great work.—Dr. A. G. GILLAN, Dr. W. WHITFORD, Dr. J. HILL ABRAM, and Dr. H. ARMSTRONG also spoke.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society was held on Feb. 7th, Dr. A. R. Galloway, the President, being in the chair.—Dr. Ashley W. Mackintosh read notes on a case of Myasthenia Gravis. The patient was a woman, age 31 years, with no nervous family or personal history, who began to show bulbar symptoms (difficulties of articulation, swallowing, and mastication) along with diplopia, ptosis, and external ophthalmoplegia; great general weakness of the limbs and ready exhaustion of muscles on exertion soon appeared. Under treatment the general condition of nutrition markedly improved but the limbs remained weak and easily tired. No sensory disturbances, no trophic signs, no fibrillary tremors, and no rigidity appeared at any time, and the sphincters were quite intact. Apart from occasional head pain none of the general symptoms of cerebral tumour were present. The involvement of the cranial nerves was very marked. There were double ptosis and external ophthalmoplegia, profound paralysis of the upper facial muscles and of the elevators of the lower jaw, great weakness of the lower facial muscles with the "rasal smile of Gowers," and great difficulty of articulation, mastication, and swallowing, the lips, tongue, and palate being markedly involved. There was weakness of the respiratory muscles with weak and useless cough. The tongue appeared to become smaller and somewhat wrinkled. The orbicularis palpebrarum gave the myasthenic reaction. Many of the symptoms varied greatly in severity from time to time and most of them were aggravated by continued use of the muscles involved. An alarming attack of syncope without any apparent cause took place, followed by a tendency to attacks of dyspnoea, and death ensued ten days later from collapse of the lung and aspiration pneumonia. The duration of the illness was about 11 months. No necropsy was permitted. The differential diagnosis was discussed at some length, special attention being drawn to the

difficulty of distinguishing myasthenia gravis from hysteria and chronic bulbar paralysis. Remarks were made on recorded observations which had been made on the morbid anatomy of myasthenia, on the probable seat of lesion, and on the pathogenesis of this condition. It was believed that at present they could only agree with Gowers in regarding myasthenia as a nutritional disorder impairing the vital processes in the muscle, although Farquhar Buzzard's observations on the constancy of slight changes in a limited number of muscular fibres in every one of his cases were regarded as suggestive.—Dr. Peterkin read a paper on the Treatment of Acute Otitis Media. He first remarked on its very common occurrence and on it being almost always the forerunner of the chronic suppurating condition which was a menace to the efficiency and safety of the sufferer. The frequency of this chronic suppurating was due to the fact that physicians did not see a large number of the acute cases until too late, but also many physicians did not treat them as the serious condition which they undoubtedly were. He said that the treatment of acute otitis media was divided into two stages—that before and that after perforation of the tympanic membrane. During the acute stage the relief of pain was the most urgent requirement of treatment; for this one of the best remedies was a solution of carbolic acid in glycerine, 10 or 20 grains to the half ounce, with or without the addition of 10 grains of cocaine hydrochlorate. A few drops of this solution warmed and instilled into the ear every hour or two generally brought relief. Where it failed ear baths might be used. This consisted in filling the meatus with hot boric acid solution and allowing it to remain for a few minutes; this was repeated every hour or two and in the intervals hot boric fomentations were applied over the ear. Poultices were unhesitatingly condemned on account of their tendency to encourage sloughing. As internal remedies, particularly where the temperature was raised, an analgesic antipyretic was frequently useful and an opiate would probably be necessary in the evening. If those remedies failed there still remained free incision, not puncture, of the membrane. This very rarely failed to give relief. It relieved pain by relieving pressure, allowed the discharge to escape, and was the best site for bleeding. In the milder cases a vertical incision in the posterior inferior quadrant was sufficient, but in the more severe cases the incision ought to be carried up the whole extent of the drum and on to the posterior superior wall of the meatus. Incision ought to be done if the preliminary treatment did not give relief in 24 hours. When, however, there were indications for an earlier incision it ought not to be postponed. Such indications were a bulging membrane, high temperature, vomiting, convulsions, or any signs of cerebral irritation, and also any marked mastoid tenderness. The drum ought also to be incised at once in otitis media occurring in the course of the zymotics. The most useful local anæsthetic was one composed of equal parts of menthol, cocaine hydrochlorate, and carbolic acid. After the membrane had ruptured or been incised treatment must be directed to the promotion of drainage from the middle ear. Frequently syringing with a warm, mild antiseptic such as boric acid was enough to bring about healing, but if discharge continued after some days of this treatment peroxide of hydrogen might be used. This was best done before syringing so as to prevent irritation of the meatus. In the few cases where even this was not enough to effect a cure boric spirit drops used after syringing would frequently benefit the case. This was only to be used after all signs of acuteness had disappeared. It was advisable in using these drops to practise tragal massage until the spirit was felt in the throat. The insufflation of boric powder was not good as routine treatment. It might lead to the blocking up of discharge and even cause mastoid abscess. As to mechanical aids to drainage, middle-ear inflation ought not to be done while there was much pain, but although there was considerable diversity of opinion as to its use after pain had ceased Dr. Peterkin advocated its use. Young and Milligan's experiments on the cadaver were unsatisfactory and they had not proved their objection to the practice. The application of suction to the middle ear was another mechanical method of treatment which was complementary to inflation and did not replace it, as the opponents of inflation stated. The treatment of any lesion of the throat and nose was of the utmost importance and where it was non-operative it ought to be undertaken at once. Operative treatment, such as the removal of adenoids, ought to be undertaken so soon as the temperature had become normal;

this age. No grounds were found for supposing the parathyroids to be affected in Graves's disease or in tetany. The occasional resemblance of parts of a parathyroid to the foetal thyroid was noted. The general conclusion was that the observations lent support to the view that the parathyroid was able when necessary to assume thyroid functions rather than to the view that it had a function of its own entirely unconnected with the thyroid and absolutely essential to the continuance of life.

OPHTHALMOLOGICAL SOCIETY.

Exhibition of Cases and Specimens.

A CLINICAL meeting of this society was held on Feb. 14th, Mr. R. W. DOYNE, Vice-President, being in the chair.

Mr. LUDFORD COOPER showed a case of Paralysis of the Vertical Movements of Both Eyes. The patient was a man in whom there was complete paralysis of the vertical movements of both eyes which had come on suddenly and for which no explanation could be found.—Mr. J. H. FISHER had seen two similar cases, one in a girl who was found one morning unconscious with this paralysis. She recovered consciousness rapidly but the paralysis persisted for a long time. The explanation he then gave was an embolism of one of the small arteries of the corpus quadrigeminum. The other case showed hemianopic pupil reaction without a hemianopic field, a condition never before recorded, and post mortem a diffuse growth of the lamina quadrigemina was found.

Mr. A. STANFORD MORTON showed a case of a man, aged 54 years, who two years previously received a steel foreign body in his right eye. The sight of this was immediately affected. About a month later the sight of the left began to fail and within three months was almost completely lost. Now the right eye showed typical siderosis, with atrophy of the nerve. The left eye showed a similar condition of the disc, the atrophy being of the post-neurotic type. There was marked arterial sclerosis in both eyes. The left pupil showed the Argyll-Robertson reaction. No sign of central nervous disease could be found.

Mr. MALCOLM L. HEPBURN showed a case of a man, aged 61 years, with Polycoria associated with Chronic Glaucoma. The sight of the right eye had become dim recently, though for the last three years he had noticed coloured rings round the lamps. He had had no pain. The left eye was normal in every respect. The right eye showed an unusual appearance of the iris which, he stated, had been present from birth. There was a complete pupil placed down and in which reacted to light, while the part between the pupil and the periphery was made up of five triangular-shaped bands of pigmented iris tissue, with their bases towards the angle. These bands inclosed clear spaces, through any of which the details of the fundus could be plainly seen. In addition to these bands an almost complete circular stump of pigmented tissue was visible at the angle of the anterior chamber, in which the bases of the different bands were lost. The patient stated that the pupil used to be in the centre of the eyeball, but of late years it had gradually come to occupy its present position. The fundus showed glaucomatous cupping of the disc. The case was interesting from a developmental point of view and two explanations were possible—one that the iris was originally complete and by subsequent atrophy, as the result of inflammatory action or otherwise, had partially disappeared; the other was a faulty development, which was difficult to understand, since the pupil was perfectly formed.—Mr. E. TRACHER COLLINS suggested as a possible explanation the failure of the formation of some of the loops of vessels which go to form the iris.

Mr. WARREN TAY showed a drawing of an Eye from a case of tuberculosis which was only diagnosed after an ophthalmoscopic examination had been made. This occurred 22 years ago. He showed this in order to disprove the statement of an eminent physician who stated that this had never been done.

Mr. J. H. TOMLINSON showed a Retinoscopy Longarm to facilitate the practice of retinoscopy in children.

Mr. W. HALLIBURTON McMULLEN showed a case of Detachment of the Retina cured by two scleral punctures.

Other cases were shown by Mr. G. W. THOMPSON and Mr. G. H. POOLEY.

LIVERPOOL MEDICAL INSTITUTION.

Submucous Resection of the Nasal Septum.—Pulsating Exophthalmos; Ligation of the Common Carotid Artery.—Housing of the Working-classes in Liverpool.

A MEETING of this society was held on Feb. 14th, Mr. FRANK T. PAUL, the President, being in the chair.

Dr. W. PERMEWAN read a paper on Submucous Resection of the Nasal Septum. He described in detail and illustrated by lantern slides reproduced from Dr. StClair Thomson's drawings the method introduced by Killian of Freiburg and then briefly indicated the procedure adopted by Freer of Chicago. Dr. Permewan insisted on the advantage of operating under cocaine, without a general anæsthetic, and said that there was practically no pain, no shock, and no hæmorrhage. He thought that a satisfactory result could always be predicted if the operator had sufficient experience and sufficient patience, but the operation should not be undertaken by anyone unskilled in nasal surgery. He then demonstrated the operation on a dissected specimen and showed the instruments used.—Dr. J. E. McDUGALL thought the submucous operation had a great future before it. He considered it an interesting speculation whether the efforts which had been made in recent years to establish free nose-breathing in children would reduce the frequency of intranasal operations in later life.—Mr. T. GUTHRIE could corroborate what Dr. Permewan had said as to the great value of the operation. He asked what Dr. Permewan considered to be the earliest age at which the operation should be performed. Freer regarded it as suitable for all ages, but stated that in children a recurrence of the deformity was probable unless the operation was a very thorough one. Was there any risk that in children the operation would involve a subsequent dropping of the bridge of the nose?—Dr. J. BARK and Mr. T. C. LITTLE JONES also spoke.

Dr. A. NIMMO WALKER showed a case of Pulsating Exophthalmos successfully treated by Ligation of the Common Carotid Artery. The patient, a married woman, aged 29 years, had been admitted into St. Paul's Eye and Ear Hospital in May, 1906, with the history that six weeks previously she had been struck on the left temple by a large piece of wood, and on the following day had noticed a swishing noise in the head which became gradually worse, with increasing swelling of the left eye. The left eye was found to be proptosed, with dilated episcleral veins, hazy cornea, and cedematous conjunctivitis, while the right eye also was congested and prominent; pulsation could be felt in both eyes and, with the murmur, was controlled by pressure on the left common carotid. The artery was tied and a month afterwards the eyes were about normal. At the present time, eight months later, the only abnormality was enlargement of the episcleral veins of the left eye, the sight of which had recovered from doubtful perception of light to normal vision with the help of a correcting lens; the vision of the right eye had always been normal. Dr. Walker thought that in this case the artery had leaked into the cavernous sinus, but that this, far from being a contra-indication to operation, as had been previously taught, was indicative of its immediate necessity; whether the lesion was aneurysm or aneurysmal varix early ligation was recognised now as the right treatment, a result largely due to the teaching of his father, Mr. G. E. Walker, who had advocated this operation ever since his first case in 1878.

Dr. E. W. HOPE, medical officer of health of Liverpool, gave an account of the position of the city in regard to insanitary property and the measures taken by the corporation to deal with it. He explained the reasons in connexion with the rapid growth of the city which led, during the early part of the last century, to its development upon lines resulting in the erection of many thousands of dwellings of an insanitary character. A heavy legacy of insanitation had thus been left for future generations to deal with. In 1883 a special committee was appointed to deal with the masses of insanitary property existing in the city and from that year onwards, at varying rates of progress, the work had been proceeded with under the provisions of the Liverpool Sanitary Amendment Act. Dr. Hope explained the difficulties which had to be contended against and stated that upwards of a million sterling had been spent by the corporation in removing insanitary dwellings and re-erecting suitable habitations upon their

mastoid abscess following right middle-ear disease on Dec. 4th, 1906. Attacks of *petit mal* had been observed for a year. After operation drowsiness supervened and a left-sided convulsion followed by hemiparesis. There was no headache, vomiting, or optic neuritis. Granulations were found blocking the opening from the antrum into the tympanum and removed but the dura mater was found to be healthy; the drowsiness and weakness then disappeared. Ten days later headache and drowsiness came on and a needle inserted into the temporo-sphenoidal lobe showed pus; the abscess was drained and recovery was then uneventful.

—A girl, aged three years, with Undue Mobility of the Right Knee-joint was shown by Dr. F. J. Poynton. If semiflexed she could voluntarily move the tibia outwards and slightly forwards over the femur and back again into position. The movement was apparently due to the popliteus muscle. There was considerable laxity of the lateral and crucial ligaments. The movement was accompanied by a clicking sound. When the limb was extended there was no lateral movement and walking was not interfered with. The articulations of the wrist and fingers were to a lesser degree more mobile than natural. —A case of "Punch"-like Intonation in a Syphilitic Infant was shown by Dr. G. A. Sutherland. The child, aged three years, had been blind since birth and could not sit or stand. He was small and flabby and markedly rickety, with syphilitic scarring round the mouth. There were post-neuritic atrophy of the optic nerve and general choroidal atrophy. His speech, which was unintelligible, was squealing or "Punch"-like. The larynx appeared to be normal. Dr. Sutherland had seen a similar case in a hydrocephalic infant. —A case of Infantileism was shown by Dr. L. A. Olutterbuck. The patient was a girl, aged 13½ years. She was intelligent but did not know her letters. She was only at school for a year up to about eight years of age. Her height was 3 feet 4½ inches and her weight was 2 stones 6½ pounds. The breasts were quite undeveloped. There was no history of syphilis or of consanguinity in the parents.

LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society was held on Feb. 1st, Dr. Augustus H. Bampton, the President, being in the chair. —Dr. G. Newton Pitt read a paper on the Value of Blood Examinations to the General Practitioner. —Dr. C. H. Melland gave a lantern demonstration illustrative of the Conditions of the Blood in Health and Disease. —Dr. T. Churton showed a case of Anæmia Splenica Infantum. —Dr. T. W. Griffith showed a case of Pernicious Anæmia in which there was Enlargement of the Spleen. —Mr. H. Bailey and Dr. W. H. Maxwell Telling showed a case of Chronic Lymphatic Leukæmia in which there was Massive Enlargement of the Glands all over the body. —Mr. H. Littlewood showed a patient in whom Removal of Malignant Growths occurring simultaneously in the Splenic Flexure and Rectum had been successfully performed. —Dr. A. S. F. Grünbaum showed some Preparations of *Spirillum Gallinarum*, *Piroplasma Canis*, and *Trypanosomes*. —A meeting was held on Feb. 15th, the President being in the chair. —Dr. Telling and Mr. C. C. Gruner communicated a paper on Actinomycosis, with notes of some unusual cases. In one case the disease had affected the back of the hand of a woman, aged 24 years; it was regarded as tuberculous and had resisted surgical and x ray treatment for two years; it readily cleared up on the administration of large doses of iodide of potassium (reaching six drachms a day at one time), combined with daily immersion in baths of hot lotion of biniodide of mercury of strength 1 in 2000. In another case the disease had affected the external and middle ear and the mastoid cells. A radical mastoid operation was performed by Mr. G. Constable Hayes and this, combined with the administration of iodide of potassium, had brought about rapid recovery. Three cases of the disease affecting the abdomen were also described and the clinical and diagnostic features of the disease as it affected the abdominal viscera were discussed. —Mr. B. G. A. Moynihan read a paper entitled "Remarks upon the Treatment of Acute Appendicitis." He drew attention to the occurrence of intestinal peristalsis after the swallowing of fluids. A case was detailed in which an intestinal fistula existed and where it was found that in a period varying from one and a half to three minutes after the drinking of any fluid a peristaltic ejection of intestinal contents was accompanied by the abdomen. It was pointed out that water was not absorbed

at all from the stomach, having to pass always through the pylorus into the intestine, and so starting a peristaltic wave which travelled through the intestine. Cases were referred to in which milk, or water, was recovered in full from a high jejunal fistula within five minutes of being taken. The importance of peristaltic unrest in disturbing an inflamed appendix was emphasised. To secure rest to the appendix absolute starvation of the patient for several days was necessary; in practice there was rarely any difficulty in carrying out this treatment. But above all in importance in the treatment of acute appendicitis was the necessity of avoiding aperients. Cathartics given in acute appendicitis were responsible for many of the serious complications of the disease; they increased peristalsis and added to the bacterial virulence of the intestinal contents, at that place more particularly where microbic life was most abundant—namely, the ileo-caecal region. In acute perforative appendicitis a history could almost invariably be obtained which showed that the acute outbreak of the disease was due to an aperient. When peritonitis was profuse an operation should be performed at once and the principles advocated by Dr. J. B. Murphy scrupulously observed. These were rapid removal of the appendix; avoidance of exposure or damage to any intra-abdominal viscera; drainage through the original incision and through a median abdominal incision; the propping up of the patient in the sitting posture, and continuous rectal infusion. A vaginal tube introduced into the rectum was connected with a receptacle, slightly elevated and containing saline fluid warmed by a spirit lamp. Fluid trickled slowly into the rectum and was absorbed at the average rate of one pint an hour. In his own cases from five to 11 pints were given; then the flow was discontinued for an hour or two and restarted, after a turpentine enema if such were needed. Mr. Moynihan had operated by this method upon 15 successive cases, with one death. —Dr. J. B. Hellier showed a Child born without Eyes. —Mr. Michael A. Teale showed a case of Recurrent Transient Proptosis of the Right Eye. —Mr. Littlewood showed a patient who had been operated on for Malignant Disease of the Tongue and the Scrotum occurring simultaneously. —Dr. Telling showed a Thrombus of gradual ante-mortem formation occluding the aortic arch. —Other specimens and cases were also shown by Mr. J. Stewart, Mr. H. Secker Walker, Dr. A. Bronner, Mr. Gruner, Mr. R. Lawford Knaggs, Mr. Hayes, Dr. E. F. Trevelyan, and Dr. L. A. Rowden.

ROYAL ACADEMY OF MEDICINE IN IRELAND.—A meeting of the Section of State Medicine was held on Feb. 8th, Dr. F. C. Martley, the President, being in the chair. —Dr. Thomas Donnelly read a paper on the Report of the Viceroyal Commission on the Poor-law. He chiefly dealt with the report as it affected the Poor-law medical service. With regard to the proposal to form a State medical service he said that the representatives of the people did not want it, while the medical profession were divided in their opinion, although not satisfied with their present position, but in his opinion these different views ought to be capable of adjustment. He approved of the proposal to establish county hospitals and smaller district hospitals; the latter he thought ought to be established in every dispensary district, while the county hospitals ought, in his opinion, to have an out-patient department attached to them and be the dispensary for the district. Dr. Donnelly then passed on to the consideration of the salaries of the medical officers in the proposed service, which he thought ought to commence at £200 per annum, rising to £400, with fees and a residence rent-free. The medical officers should be entitled to an annual holiday of one month and retirement after 20 years' service ought to carry with it a pension equal to half the total salary of the medical officer and after the age of 65 years he should be entitled to a pension equal to two-thirds of his total salary. The next point considered in the paper was the board of control, as proposed in the report. This he strongly objected to as likely to raise the greatest opposition to the scheme and advocated instead that all appointments should be in the hands of a committee elected by the county council. As regards entrance to the service Dr. Donnelly thought that all the medical officers ought in addition to their ordinary qualifications to have special certificates in lunacy and obstetrics and to have passed 12 months as locum-tenents in the service. —Professor E. J. McWeeney read a paper on the Policy with regard to Tuberculosis outlined in the report of the Viceroyal Commission on the Poor-law. He began by referring to the increase of tuberculosis in

it ought not to be put off until the otitis was cured. If discharge still continued from the ear, and as the patient might not know whether the ear was discharging or not the physician ought to see to it personally, at the end of six weeks the mastoid antrum ought to be opened. It was a mistake to wait for the classical symptoms of mastoid disease, as the patient might be very deaf before these appeared.

MIDLAND MEDICAL SOCIETY.—A meeting of this society was held on Feb. 13th, Dr. Arthur Foxwell, the President, being in the chair.—Mr. R. H. Rollinson-Whitaker showed a case of Graves's Disease in which he had tied the two superior thyroid arteries. The patient, a woman, aged 46 years, had suffered from Graves's disease for 15 years, and had for the last four years been practically bedridden. She had been unable to walk more than a few steps and those with great difficulty and often unable to feed herself from weakness and tremor. An operation, undertaken after three months' treatment in a nursing home, was performed under a local anæsthetic. After 48 extremely anxious hours, during which the patient showed signs of commencing acute thyroidism, great restlessness, vomiting, delirium, temperature 102° F., pulse 180, and respirations 44, she commenced to improve rapidly. 16 days after the operation pulsation in the thyroid had almost disappeared, the gland had diminished in size by four inches, and the pulse had fallen to 100. The general condition had gradually improved up to the present time when the patient was able to attend to her household and social duties and to walk considerable distances in all weathers.—Mr. W. Billington showed a case of Leontiasis Ossea in a girl, aged 19 years, who presented symmetrical bony outgrowths on each side of the nose. The nasal processes of the superior maxillæ were chiefly involved. Her facial appearance was typically leonine. The nasal ducts were obliterated and there was commencing nasal obstruction. The girl was a congenital syphilitic. The disease began six months ago and had progressed steadily and painlessly.—Mr. A. Lucas and Mr. J. Hall-Edwards showed a case of Lymphadenoma treated with Marked Improvement by the X Rays. The patient was a middle-aged man, with large masses of glands in the neck on the left side, in the left axilla, and in the left groin. He was exceedingly emaciated, cachectic, and so feeble that he could hardly stand, his breathing becoming laboured on the slightest exertion. The patient had not responded to ordinary therapeutical measures but after a fortnight of x ray exposures he commenced to improve and at the end of two months all the glands had disappeared and this disappearance of the glands was associated with a very marked improvement in the general condition, so that at the present time the patient was able to take long walks without undue fatigue.—Dr. J. G. Emanuel showed a case of Hyperidrosis. The patient was a man, aged 53 years, who had been troubled with a profuse sweating, after any exertion, affecting the left half of the face, head, and neck, and upper part of the trunk as low down as the intermammary line, an area corresponding to the distribution of the sweat fibres in the cervical sympathetic. The condition followed a severe attack of influenza and had persisted unchanged for two and a half years. The pupils were equal and reacted equally to light, accommodation, shade, and cocaine. There were no exophthalmos and no retraction of either lid. The question raised was whether this was due to partial paralysis of the right cervical sympathetic, with anidrosis of the right side of the face and a compensatory hyperidrosis of the left side, or to irritation of the left cervical sympathetic, or to a neurosis of central origin.—Mr. J. Furneaux Jordan showed two specimens. The first was a large, soft, cedematous Fibroid of the Uterus removed from a woman, aged 48 years, who had suffered so severely from hæmorrhage that she could not sit up without fainting and since it continued under treatment and rest in bed operation was imperative. Her convalescence was prolonged. The second specimen was a large, pure Fibromyoma of the Right Ovary removed from a woman, aged 59 years. It was associated with great hydro-peritoneum and an umbilical hernia. The recovery was good.—Dr. J. Miller showed Blood Films from a case of Leukæmia. The patient was a man, aged 46 years, who died after an illness of some three or four months in which breathlessness, lassitude, hæmorrhages from mucous surfaces, irregular temperature, and an enlarged spleen and liver were prominent features. Three weeks before death the blood count was as follows: red corpuscles, 1,500,000; white corpuscles, 30,000;

hæmoglobin, 22 per cent.; and colour index, 0.73. There was marked poikilocytosis with macrocytes and microcytes, and numerous nucleated reds, of which a large proportion were megaloblasts. Of the leucocytes a considerable proportion were myelocytes, both finely and coarsely granular, and there were many basophiles and large lymphocytes. The spleen weighed 40 ounces and microscopically showed a typical leukæmic condition with multiplication of the endothelial cells and some fibrosis. The liver gave the iron reaction.—Dr. O. E. Pursalow showed: 1. An Ovarian Cyst which had undergone spontaneous rupture. The patient had noticed a gradually increasing swelling of the abdomen for five months and two weeks before admission had been seized with sudden severe abdominal pain and vomiting lasting three days. The abdomen was opened and a gallon of free fluid escaped from the peritoneal cavity; the cyst was removed after tying its pedicle; it contained a small quantity of similar fluid and there was a free opening on its upper aspect. It proved to be a multilocular papillomatous cystoma. The patient made a good recovery. 2. A Cystic Kidney which before removal had exactly simulated an ovarian cyst. The specimen was from a single woman, aged 37 years, who had noticed a gradually increasing tumour in the abdomen for two years. There were no other symptoms and it was not till the abdomen was opened that the true nature of the tumour was ascertained. The peritoneal investment was divided, the tumour emptied by means of a trocar and then enucleated, and the pedicle tied. No drainage was employed. The patient made an uninterrupted recovery.

SOCIETY FOR THE STUDY OF DISEASE IN CHILDREN.—A meeting of this society was held on Feb. 15th, Mr. Sydney Stephenson being in the chair.—The following cases were shown and discussed. Mr. Stephenson showed a case of Buphthalmos. The patient was a syphilitic child, aged ten months. The condition had been observed immediately after birth. The corneæ, which had been extremely cloudy, had cleared under treatment by physostigmine and mercury internally. Moreover, the operation of anterior sclerotomy had been performed upon the left eye. The child retained fair sight.—A case of Cretinism was shown by Dr. E. I. Spriggs and Dr. F. W. Higgs. The child, who was two years and seven months old, had always been backward. She was 26 inches high; the circumference of the head was 17½ inches. She could not walk or stand and was a typical cretin physically. The mind was equal to that of a normal infant of eight months. The complexion had already improved markedly since thyroid treatment was begun only three weeks ago. One grain of the extract was given three times a day. The weight fell half a pound and there were considerable restlessness and fretting, which ceased when the dose of thyroid was lessened.—A case of Cerebral Tumour was shown by Dr. Edmund Cantley. The patient was a boy, aged ten years. For six weeks he had had attacks of headache lasting 12 hours and terminating in vomiting about once a week. For two weeks he squinted, this being due to paralysis of the left external rectus. He had optic neuritis and exaggerated knee-jerks but no other abnormal signs were found on examination. Dr. Cantley suggested a small quiescent tuberculous focus in the superficial portion of the pons. Dr. Cantley also showed an infant, six weeks old, with a huge Inguinal Hernia in conjunction with basal meningitis. The condition of rigidity of the abdominal muscles made it doubtful if an operation should be done at present for the cure of the very large inguinal hernia.—A Lymphangioma or Lymphatic Nevus of the Left Side of the Tongue was shown by Mr. J. P. Lockhart Mummery. The patient was a boy, aged five years. The surface of the tumour showed small clear-walled cysts. It caused no inconvenience.—Three cases of Aortic Regurgitation were shown by Dr. J. Porter Parkinson; they were all in girls and of rheumatic origin. In one patient, aged nine years, there were aortic diastolic and mitral systolic murmurs. In the second case (aged 12 years) there was only an aortic regurgitant murmur with enlargement of the left ventricle, water-hammer pulse, and well-marked extensive visible arterial pulsation. In the third case (aged 14 years) similar signs were present, but in addition there were a presystolic and thrill at the apex of the heart and presystolic and systolic murmurs in the same situation; the pulse was of moderate size, indicating that there could be little, if any, mitral stenosis.—A case of Cerebral Abscess after operation was shown by Mr. P. Turner. The patient, a girl, aged seven years, was operated on for an acute

general health and by the "guarded attitude" in which the spine was held; the grunting respiration elicited by placing the child in a prone position across the knees was distinctive and more reliance should be placed on distal or radiating pains than on local pain. Muscular rigidity limited to a few vertebrae preceded the bony rigidity with general contraction of the spinal muscles. It was necessary not to confuse lateral curvature with posterior projection of the spinal processes with a lateral curve due to unilateral caries of the vertebral bodies. In the matter of treatment it was pointed out that the case required a recumbent posture for years rather than months. He had been disappointed with the results of laminectomy for compression paraplegia, finding that recovery followed rest in most cases, while laminectomy was of little value except where pus could be evacuated. He was less inclined than formerly to treat abscesses by incision and drainage, preferring to close the wound and to treat it aseptically. The immediate reduction of spinal deformity by successive stretchings was of value, but owing to the great difficulty, especially in out-patient practice, of obtaining prolonged rest most cases relapsed. The differential diagnosis from rickety kyphosis was alluded to and models and drawings of apparatus were shown with photographs of various types of deformity. In dealing with the causes of lateral curvature attention was drawn to the influence of unequal legs, and the difficulty of diagnosis and treatment in cases of crossed asymmetry was mentioned. The treatment fell under the four headings of rest, exercise, massage, and support. Two schools of treatment had arisen, by exercise and by supports, but in the opinion of Mr. Tubby every case could not be adequately treated by either method. Discretion must be used in the choice of treatment and in some both methods might be combined with advantage. Deformed chests, spasmodic wryneck, and coxa vara were briefly referred to, the importance of prolonged rest in cases of osteotomy for genu valgum was insisted on, while the futility of operating in genu valgum of ligamentous origin was shown. The various forms of flat-foot were discussed and explained, splints and supports of different kinds were shown, and the good result following the excision of an inch of the peroneal tendon in some cases was alluded to.

WIGAN MEDICAL SOCIETY.—A meeting of this society was held on Jan. 15th, Dr. Ferdinand Rees, the President, being in the chair.—Dr. A. E. Hodder read a paper on Proliferic Obstruction.—A discussion followed in which Mr. C. M. Brady, Mr. William Latham, Dr. Blair, Dr. M. Benson, the President, and others took part.—A presentation was then made to the past-President, Dr. Blair.—A clinical meeting was held on Feb. 14th in the Royal Albert Edward Infirmary, Wigan.—Mr. Brady read notes of a case in which he had sutured the External Popliteal Nerve three years and ten months after division.—The President showed a case in which after the skull had been trephined for Jacksonian epilepsy no lesion was found but the attacks had ceased. The patient was a boy, 13 years of age, and it was now two years since the operation.—Mr. Berry showed a case of Rupture of the Quadriceps Extensor Femoris Muscle at its junction with the patella in a man 50 years of age.—Mr. E. H. Monks showed an Ovarian Cyst which he had removed from the broad ligament.—Dr. R. Prosser White showed cases of Lupus Vulgaris and of Rodent Ulcer.—Mr. Hugh E. Jones and Dr. Harry Holmes showed cases of Excentral Contraction of the Conjunctiva, Zonular Cataract, Chronic Glaucoma, Sloughing Ulcer with Hypopyon, Iritis with Tension, Dislocation of the Lens, and Needling for High Myopia.

NEWCASTLE-ON-TYNE CLINICAL SOCIETY.—A meeting of this society was held on Feb. 7th, Mr. G. Foggins, the President, being in the chair.—The following cases and specimens were exhibited.—The President: (1) A man, aged 27 years, with old-standing Dislocation of the Lens in the Left Eye; (2) Retinal Haemorrhage in a boy, aged 13 years, the subject of letter blindness; and (3) photographs of cases in the special school for defective-minded children.—Dr. W. E. Alderson: A case of Tertiary Syphilitic Disease of the Tongue in a woman.—Mr. H. B. Angus: (1) Excision of the Knee, followed by irregular growth resulting in marked genu varum; and (2) Contusion of Popliteal Vessels by Fracture of the Femur followed by Gangrene.—Mr. J. W. Leech: (1) Malignant Growth, probably Sarcoma, in the Neck; (2) Tumour in the Groin; (3) Two cases of Tuberculous Dactylitis; (4) Ectopia Vesicae in an infant;

(5) Hypospadias in an infant; (6) Chronic Tumour; and (7) Tuberculous Abscess of the Chest Wall.—Mr. J. Clay: (1) Case of Coxa Vara, with x ray photograph; (2) Ectopic Gestation; and (3) Syphilitic Testicle.—Mr. G. G. Turner: Villous Growths removed from the Bladder, a series of four specimens with illustrative notes. Mr. Turner concluded that as the history of nearly every advanced case of malignant disease of the genito-urinary tract was notable for the occurrence of early neglected haemorrhage, a single attack of urinary bleeding, if not clearly depending on nephritis, demanded cystoscopic examination.—Dr. A. J. Collis contributed a paper on Some Notes on Circumcision, which led to an interesting discussion on the methods of operation and after-treatment of a surgical procedure characterised as one of the very few still left to the general practitioner.—The Secretary, Mr. Leech, drew the attention of members to the fact that the annual address, on Some Recent Theories of Diet and their Bearings on Practical Medicine, would be delivered on April 4th by Dr. Robert Hutchison of the London Hospital.

Reviews and Notices of Books.

Leçons de Thérapeutique Oculaire, basées sur les Découvertes les Plus Récentes. (Lectures on Ocular Therapeutics, based on the Most Recent Discoveries.) By Dr. A. DARIER, formerly President of the Society of Ophthalmology of Paris. Paris: Published at the Bureau of La Clinique Ophtalmologique. 1907. Pp. 400. Price 12fr. 50c.

THIS book is the third edition of Dr. Darier's lectures on ocular therapeutics, the second edition, which was translated into English by Mr. Sydney Stephenson, having been published five years ago. Dr. Darier is one of those enthusiasts who delight in new things. Enthusiasm is ever liable to outrun discretion and Dr. Darier's proves no exception to the rule. He has been wise in the choice of his medium for expounding his views, for the lecture room permits of a freedom of expression and picturesqueness of diction which would be out of place in a text-book. Perhaps the value of the work would have been enhanced by greater restraint and by more judicious utterance. Of the 25 lectures the first 15 are devoted to the discussion of new methods and new drugs, the remaining ten dealing with conjunctivitis, diseases of the cornea, and tuberculous disease of the eye. Diseases of other parts of the eye are referred to incidentally but we gather that they will form the subject of a second volume, as yet unpublished.

The first lecture is introductory, pointing out the "banality and insufficiency" of modern ocular therapeutics, with its "omnipotent triad"—atropine, silver nitrate, and mercury. The second lecture deals with the methods of general therapeutics, especially mercurial medication by the mouth, by inunction, and by hypodermic, intramuscular, and intravenous injection. A brilliant future is prophesied for intravenous injections such as mercury cyanide, biniodide, salicyl-arsenate, and so on. "It is well after a first series of 30 injections to allow a month's rest before resorting to a second or even a third series." In such conditions as interstitial keratitis and choroiditis "it may be necessary to give more than 100 or 200 injections in the course of two or three years." *Toujours l'aurore!*

The third and fourth lectures are occupied with a discussion about local medication, especially subconjunctival injections, for which the author expresses "quite a paternal affection." Some space is devoted to explaining the almost negative results of experimental observations on animals. The effects of sodium chloride, cyanide of mercury, sodium salicylate, and other subconjunctival injections are passed in review.

The remaining eleven lectures in the first part of the work are allotted to various applications to the conjunctiva. These are divided according to their action in modifying the

Ireland mentioned by the Commissioners in their report. The explanation was no doubt that in Ireland very little was being done and that sporadically, whereas in England, amongst other factors, the efforts of independent, whole-time county medical officers of health produced results which could not be hoped for under the excessively bad system which in Ireland placed the health officer's interest in direct opposition to his duty. The recommendation of the Commission that the disused workhouses should be converted into consumption sanatoriums deserved hearty approval. It was a wise suggestion of the Commission that not only curable but advanced and infective cases should be removed to the contemplated sanatoriums. The removal of such patients from their homes was one of the essential parts of the campaign against the disease but in Ireland it would be objected to if there were not some prospect of recovery held out. By proper classification and rigid observance of regulations he thought that the association of curable and advanced cases in one institution might be rendered unobjectionable. The suggestion of the Commission that consumptive inmates of lunatic asylums should be segregated in a few specially adapted workhouse sanatoriums he regarded as particularly valuable, in view of the great difficulty in rendering such cases non-infective. He thought that county councils should have a free hand in devoting public funds to sanatoriums and not be limited to a rate of 1*d.* in the £ as at present. He looked forward with confidence to the growing-up round the sanatorium of auxiliary institutions, such as volunteer philanthropic committees for providing (1) suitable outdoor or hygienic work for ex-patients so as to prevent relapse, and (2) sustenance for the wives and families of tuberculous working men, so as to secure for the latter while in the sanatorium that peace of mind which was an indispensable factor in the treatment. In Germany this need was supplied by the State invalidity insurance.—Dr. Leonard Kidd, Dr. J. M. S. Kenny, and others took part in the discussion.—The following motion, proposed by Mr. John S. McArdle, was adopted:—

That the Section of State Medicine of the Royal Academy of Medicine in Ireland desire to express its approval of the suggestion contained in the report of the Viceroyal Poor-law Commission to convert the entire Poor law Medical Service in Ireland into a national service, to be paid by the State, to be entered by a competitive examination, the members of such service to be jointly controlled by the central body and the local bodies, and that the medical profession should have one representative on the central body.

HARVEIAN SOCIETY OF LONDON.—A meeting of this society was held on Feb. 14th, Dr. Sidney Phillips, the President, being in the chair.—Mr. Raymond Johnson recorded the case of a man, aged 35 years, in whom Fatal Extravasation of Urine occurred from an ulcerated perforation of the left ureter by an oxalate calculus weighing only eight grains. The only symptoms were an attack of vomiting followed by the signs of a localised inflammation in the left iliac region, which were regarded as due to peritonitis. Operation revealed the presence of an abscess in the retro-peritoneal tissue, containing ammoniacal urine and pus. An attack of severe hæmorrhage from the abscess, which occurred on the following day, so weakened the patient as to prevent further interference and death took place on the fourth day. The abscess was found to extend along the whole length of the left ureter and in the cavity the small stone was found.—Mr. Campbell Williams remarked upon the unique character of the case and pointed out that in the urethra an impacted oxalate of lime stone produced more distress than either a phosphatic or uric acid concretion.—Dr. T. B. Hyslop read a paper on Psychorhythm and Recurrent Psychoses. He dealt with cases characterised by recurrence at fairly constant intervals. The exaggerations of the psychorhythmic process which tended to cross the borderline of insanity might be described as perversions of mind due to: (1) deprivation of the factors pertaining to complete consciousness; and (2) faults in metabolism and toxæmia. In the former group the most interesting cases were those of partial consciousness. In childhood night-terrors or somnambulism might precede a condition in which during the daytime there were moral or volitional perversions of which the fully awake state there was no memory. The condition of double personality was not well recognised; there were several main groups. In complete alteration the personality of the individual was entirely different in the two states; there was no continuity of thought and the memory of one state was absent during the occurrence of the

other. In the partial types the variations might depend on sensory experiences which were different from those habitual to the normal self and there might be new bodily sensations or loss of old ones, and there might be illusions of identity of part or of the whole of the individual. The anæsthetic, hysterical types were those in which the symptoms were mainly hysterical with anæsthesia and temporary amnesia; in these cases there were certain "inhibitions" which prevented the recall or the revival of the former sensations. Reference was made to some of the results of the investigations undertaken by Dr. Lewis C. Bruce upon leucocytosis in insanity.—Dr. F. J. Paynton remarked that insanities alternating with other forms of bodily ailment were conditions of great interest and alluded to a case of recurrent and obstinate priapism in which when the rash disappeared the patient became temporarily insane, to recover again when the rash reappeared. He believed that certain observations which he had made with Dr. Alexander Paine and Dr. Gordon M. Holmes might in the future assist in the elucidation of these difficult points. In six cases of fatal chorea, including one of chorea gravidarum, they had found a bacterium in the meninges, or brain, which was identical with that found in rheumatic lesions, and had found in the brain definite, though not gross, changes in the nerve cells. Some, and especially adult, cases of chorea might undoubtedly be temporarily insane.—The President, Dr. J. F. H. Broadbent, and Dr. B. H. Spilsbury also took part in the discussion.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society was held on Feb. 7th, Dr. W. C. Chaffey, the President, being in the chair.—Dr. A. W. Williams showed a case of Rodent Ulcer successfully treated by the X Rays.—Dr. C. F. Bailey showed a case of Lupus also cured by the X Rays.—Dr. E. Hobbouse showed two cases of Aneurysm of the Aorta, one of the second part of the arch with marked symptoms of pressure on the trachea, there being great dyspnoea; also there was double adductor paralysis of the larynx, which was supposed to be syphilitic in origin and not connected with the aneurysm. The second case had aneurysm of the third part of the arch, with pressure on the left bronchus and paresis of the left vocal cord, also a very small left pulse.—Dr. Walter Broadbent showed a case of Aneurysm of the First Part of the Arch of the Aorta, with pulsation to the right of the sternum and well-marked aneurysmal second sound and diastolic shock but no symptoms; the patient had been under observation for five years. He also showed a man, from whom Dr. F. J. Paley had removed a cerebellar tumour for him four years ago. The patient was blind from post-neuritic optic atrophy, but was otherwise fairly well and was earning a little money by basket making.—Mr. W. A. Bowring showed a fibroid tumour weighing 38 pounds which he had successfully removed. During the operation the right ureter was accidentally divided; he repaired it but a slight uretero-vaginal fistula had remained.—Dr. F. G. Bushnell showed some microscopic specimens of Fat Necrosis and also some pathological specimens.—Dr. Hobbouse opened a discussion on the Use of Alcohol in Medicine. He said that the first question which should present itself was, Would alcohol be of use in this illness, and will it do any harm afterwards? In acute disease alcohol was now regarded as an easily combustible food and was therefore useful at critical times when digestion was bad. He thought it was also necessary in the dyspepsia of hard-worked people and in some chronic diseases. It should never be given at the climacteric age since there was then great danger of acquiring the drink habit. It should also not be given for insomnia for the same reason. It was more valuable in old age and should then be more freely used. In rheumatism and gout it should be altogether avoided if possible.—The discussion was continued by the President and by Dr. R. Sanderson, Dr. R. J. Ryle, Dr. L. A. Parry, and Dr. Broadbent.

SOUTH-WEST LONDON MEDICAL SOCIETY.—A meeting of this society was held on Feb. 13th, Dr. M. Mackintosh, the President, being in the chair.—An address was given by Mr. A. H. Tabby on Some Common Deformities of Children occurring in General Practice. Mr. Tabby devoted the chief part of his address to a consideration of the various forms of deformity of the spine. He drew attention to the importance of early diagnosis in spinal caries before the occurrence of deformity; it was invariably preceded by a stage characterised by failure of the

meals, sleep, exercise, and such employment as children can do. The paragraph on backwardness is good but much more might have been said. For example, there are many children who, owing to late development, are backward at school and yet in later years may become able professional or business men. Referring to the more advanced education of women Dr. Clouston writes: "I would merely emphasise the fact that this higher education has often been carried on at the peril of losing something higher still. It must be made compatible with the motherhood of the race!" Later in this same chapter we read that "control is the regulator of the higher faculties and should precede them in time of first appearance." Is this statement true or would it not be more accurate to say that control is an attribute of the higher faculties?

The author strongly urges that hygiene should be taught in all schools and he considers "that the money and time given to teaching music to scholars with no ear and classics to unclassical minds would be infinitely better spent in physiological and health instruction." His views on religious training will find supporters but probably they would not satisfy any theologian, for he rather treats religion from its utilitarian advantages and not as a fundamental faith which begets the attributes which he so well describes. Special sex questions are admirably treated and in the remarks which the author makes on the subject of alcohol he reminds his readers of the recent experiments made by Professor Kraepelin of Munich and others to ascertain the mental effect of alcohol in doses that would be called moderate. Dr. Clouston considers that physical degeneration is largely brought about by city life and the fact that the children have little access to nature. The mind of the town child may be sharp, cunning, and active but his mental horizon is limited and he lacks observation and breadth of knowledge, which the study of nature alone can give. To counteract this deficiency the author urges the passing of an Act to make it compulsory for all municipalities to provide a playground near their houses for every group of 500 children of the industrial classes in our cities.

In conclusion we have no hesitation in recommending "The Hygiene of Mind" to all those who have the welfare of children at heart. Dr. Clouston is a physician of wide experience and in this book he places much of this experience at the disposal of others.

Humaniculture. By HUBERT HIGGINS, M.A. Cantab., M.R.C.S. Eng., L.R.C.P. Lond., late Demonstrator of Anatomy at the University of Cambridge, &c. New York: Frederick A. Stokes Company. 1906. Pp. 255. Price 5s. net.

By the title of this book we are to understand not the culture of "the humanities" but of mankind, and the method to be adopted is set forth in the first section of this work. Indeed, the more correct designation of this part would be "The Science and Art of Eating." The discovery was made not long ago by Mr. Horace Fletcher of the United States that the ill-health from which he suffered on retiring from business was due to incorrect habits of feeding and that his maladies vanished on adopting the practice of chewing his food more completely. As a result of this procedure he found that he was able to do with much less food and also that his palate became more delicate and his appetite more discriminating. It was to elucidate the correctness of Mr. Fletcher's doctrine that Professor Chittenden's well-known experiments were made, and it is claimed as the outcome of these that the old standard of dietary founded on Volz's work is overthrown and that much current physiological teaching is proved to be erroneous. Mr. Higgins is the prophet of the new doctrine of "poltophagy," as it is called. All food is to be chewed till it is rendered thoroughly

fluid and tasteless and is to be swallowed in this condition. If only mankind will universally adopt this simple habit most of the ills that flesh is heir to will become extinct. We are quite prepared to admit that most men eat too fast and too much; it is also definitely proved by Chittenden's experiments that men can perform hard work and maintain their weight and condition on a much smaller allowance of food than was formerly believed to be possible. But it has yet to be shown that a diet which suited Mr. Fletcher will suit all the world and that it is beneficial in the long run to exist on the smallest possible allowance of food without any margin for storage of energy or of pabulum to provide against emergencies. There even seem to be dangers ahead in any rash attempt at adopting poltophagous habits, since we read in this book of a man of science who was delighted with his first experiences of the new régime but who became seriously ill as the result of his dietetic discipline. The second part of the book contains a brief account of the history of medical doctrines, with commendation of Bouchard's views on auto-intoxication and some general reflections on hygiene and kindred matters.

LIBRARY TABLE.

Infants' Weight Chart. Designed by R. J. BLACKHAM, Captain, R.A.M.C., L.R.C.P. Edin., L.M. Rotunda, D.P.H. Lond. London: W. H. Bailey and Sons.—This chart is intended for keeping the weekly record of weight of infants during the first year of life. It measures about two feet long by one and a half feet deep and is printed in black and red ink on thin paper. Owing to its somewhat large dimensions it would be necessary to nail it up on the wall of the nursery, as it could hardly be kept in a drawer or in a case. A red line shows the normal increase in weight as estimated by Dr. E. Holt. This curve should act as a useful guide in comparing the actual increments in weight with the normal standard. There is no particularly novel feature about this chart except that it is perhaps larger and more distinct than most varieties with which we are acquainted. Every nursery should be provided with some form of weight chart and that which Captain Blackham has designed will serve excellently to fulfil all ordinary requirements.

The Writers' and Artists' Year book, 1907. London: Adam and Charles Black. 1907. Pp. 93. Price 1s. net.—The multiplicity of year-books is getting somewhat confusing, but doubtless each of them is of use to that class for which it is written. The scope of that now before us is explained by the subtitle which is "A Directory for Professional Writers, Artists, and Photographers." Within its pages will be found information as to various newspapers and magazines with indications of the kind of work with which they respectively deal.

The English Woman's Year book, 1907. London: Adam and Charles Black. Pp. 405. Price 2s. 6d. net.—This annual contains a compendium of professions, occupations, sports, and other amusements which are open to women. In this issue are included articles on Women's Suffrage, Co-education, the Civil Service, Domestic Service, and Indexing. As the volume apparently went to press in October there is naturally no mention of domestic servants being included in the new Workmen's Compensation Act.

Hazell's Annual, 1907. Edited by W. PALMER. London: Hazell, Watson, and Viney. 1907. Pp. 620. Price 3s. 6d. net.—Of all the year-books Hazell's is the most retrospective, for though it gives a great deal of information as to our own and foreign countries at the time of going to press yet the body of the book consists of a review of the events of the past year. These are well set out and though many of them deal with burning questions the *résumés*, so far as we have

superficial sensibility (anæsthetics), the deep sensibility (analgesics), the vascular tonus (vaso-constrictors and vasodilators), the muscular tonus of the iris (mydriatics and miotics), and the conjunctival secretions (caustics, antiseptics, and astringents). The anæsthetics include cocaine, eucaïne, tropacocaine, holocaine, stovaine, alypin, and others. The advantages of employing any except the first two mentioned seem to be restricted or even absent. The intraspinal injection of stovaine, which has been used with success in general surgery by Mr. A. E. J. Barker in this country, is discussed, though it appears to have nothing to do with ophthalmology. Alypin is recommended for the removal of foreign bodies from the cornea; we fail to see the advantage which it is said to possess over cocaine. The analgesics are orthoform, acoline, and dionine. Acoline finds its chief use in rendering subconjunctival injections painless. Much space is devoted to dionine, a drug which is undoubtedly of some value but scarcely merits the extravagant praise showered upon it by the author. We have not space to record the diseases in which it is indicated. Amongst the vaso-constrictors adrenalin stands alone. Its value in ophthalmic operations is fully appreciated but we have reason to doubt its efficacy in glaucoma, iritis, scrofulous kerato-conjunctivitis, episcleritis, and other conditions. There is little new in the section devoted to the consideration of mydriatics and miotics, except the enumeration of several of the later synthetic preparations. In treating of the drugs which modify the conjunctival secretions Dr. Darier confines himself almost entirely to the organic compounds of silver—protargol, argyrol, argentamin, argonin, largin, itrol, actol, and collargol. He considers that some of these compounds are as efficacious as silver nitrate, the use of which he has practically abandoned. We are unable to agree with him on this point. It may be admitted that they are less painful and that they do not act upon the epithelium. We are of the opinion that the destruction of the superficial layers of epithelium is an important factor in the utility of silver nitrate in gonorrhoeal conjunctivitis, since the imprisoned organisms are cast off with the resulting slough. We are far from denying the value of protargol in lacrymal obstruction, blepharitis, and some other conditions.

We believe that there is much of value in this book and ophthalmologists of mature experience will derive benefit from its perusal. We are, perhaps, too conservative in our methods in England but we think that Dr. Darier would have produced a more trustworthy work if he had paid more attention to his own *opiter dictum*: "*Il faut toujours se mettre en garde contre un trop prompt enthousiasme.*"

The Hygiene of Mind. By T. S. CLOUSTON, M.D. Edin., F.R.S. Edin. London: Methuen and Co. 1906. Pp. 284. Price 7s. 6d.

IN writing "*The Hygiene of Mind*" Dr. Clouston has made an attempt to put into popular language some of the known facts regarding the development of the mind, so that these facts may be used for the benefit of the race. The aim of the book, as the writer states, is practical and by this standard alone does he wish it to be judged. It is always difficult to treat a scientific subject in a popular manner, as the lay reader must have dogmatic statements and for this reason absolute accuracy must suffer. Dr. Clouston must be congratulated on the result of his labour, for although there are many points with which we should disagree, taken as a whole the book gives a lucid account of the subject. The scheme that he adopts is a very practical one, for after devoting the early chapters to the abstract study of "*the hygiene of mind*" he passes on to describe mind during its evolution and subsequent decay.

In the first chapter he discusses the scope and aims of mental hygiene and describe the way in which mind has

been developed through long stages of evolution. We agree with him that, at any rate from the practical standpoint, the basis of mental hygiene must be the study of the physiological processes of the body so far as these affect the mental functions of the brain. In the next two chapters there is a somewhat cursory description of "*The Brain and its Methods of Working.*" Some of the statements are highly speculative and are liable to mislead the lay reader. For instance, we read that "the colour and qualities of objects and their nearness or distance, the different kinds of sounds and tones, are all printed on the brain as on a book." Some of the sections in the chapter on How the Brain Mechanism Works are good, others are written in almost too popular a style, and a similar criticism may be made regarding the chapter on Principles, Essentials, and Ideals; nevertheless, the author gives many hints which will be very helpful to those whose work is that of training the young. Dr. Clouston goes thoroughly into the question of heredity and gives the views of several recent writers. He sums up the subject by saying, "that we are all agreed in regard to one important conclusion as to heredity—that is, the fact that hereditary defects may occur in two forms—the one is that of definite provable changes from the normal structure and functions of the human body. The other is that defects may occur which are not visible in early life or provable either in bodily structure or functional process, being then only tendencies and potentialities." Dr. Clouston next draws up what he considers to be the ten chief rules of mental hygiene in its relation to heredity and they are certainly valuable axioms and well worth careful study. The reference to social instincts is also good but we notice that the author does not commit himself to any definite ruling as to how to answer those who, with an insane parentage, ask advice as to whether they should marry. He evidently prefers, after pointing out the risks, to leave the decision to his applicants. Mind, Morals, and Will form the subject matter of another chapter in which, among other things, the author endeavours to prove that we must look to the man of science rather than to the moralist or the religionist for the proper understanding of mind, for he evidently feels that he can come to no other decision "if it is the case that all modern investigations done on scientific lines and tested by scientific proofs point to the conclusion that in this world mind is only manifested through brain as its vehicle and is absolutely conditioned in its every form and manifestation by brain action."

In the chapter on the Mental Hygiene of Bodily Disease we read the following statement which we cannot pass unchallenged: "Yet I have seen the most philosophic men full of delusions when the brain was touched by the *microbe* of general paralysis"; we are aware that some authorities favour the microbic theory of general paralysis but surely our present knowledge of the subject is not certain enough to permit of so positive a statement. The warnings that Dr. Clouston gives against the overdoing of games are good, for there is little doubt that the physical exhaustion which is produced in some children by prolonged exertion is very harmful.

The pages that are devoted to the consideration of the Hygiene of Work are ably written and are well worth careful reading. The author strongly urges that the speech faculty in young persons should be more thoroughly developed, as in this way they would not only acquire more accuracy in expressing ideas but the mere fact of better speech would react on the higher centres of the brain and produce keener feelings and greater intelligence. Much emphasis is laid on the importance of attending to the bodily development during the early years of life; the education in any technical sense is not recommended before the age of seven. "System, order, and punctuality" should be the rule of the child's life and this should apply to play,

THE LANCET.

LONDON: SATURDAY, MARCH 2, 1907.

Medical Education and the Examination System.

WE publish this week the address delivered on Feb. 15th by Dr. LAURISTON E. SHAW before the Hunterian Society, forming the annual Hunterian Oration of that society, in which the orator has drawn valuable lessons from the consideration of HUNTER'S career, and none the less valuable because they are so unexpected. For who would have thought that upon the life-story of HUNTER there could be founded a logical denunciation of the examination system? And yet there is much to be said for the view that the methods of HUNTER'S education, or some would say his want of education, were largely responsible for his insatiable curiosity, his practical industry, and his originality of procedure. Our present methods of medical education, in Dr. SHAW'S opinion, bid fair to destroy these qualities in our students, compelling all of them under pain of failure in examinations to work during their most receptive years solely with their eye upon examinations, and so destroying in them many of the characteristics the development of which should be the true outcome of education. Many thoughtful persons engaged directly in medical education hold the same view.

Dr. SHAW'S is a general statement. He does not enter into the vexed question of the length of the different stages of the educational course, or of the actual subjects appropriate to each stage, but the force of his words will be all the better appreciated when we remember how completely our present arrangements for instructing our medical students fail to give satisfaction to many thoughtful persons. Recent debates in the General Medical Council show that the reform of the curriculum is being seriously considered by that body. Whatever examining authority the student looks to for his degrees or diplomas the educational demands now made upon him by the curriculum are such that he finds it essential to spend the statutory five years in close touch with books; he values the instruction that he obtains from his hospital teachers mainly from the point of view of whether it will or will not assist him in an imminent examination. This means that the demands made upon students by their examinations seriously interfere with their clinical studies. The fifth year of the student's curriculum was, as we know, specially designed to be devoted to practice. Book work of all sorts at this stage was to be put behind the student's back. This was the intention of the General Medical Council when the curriculum was lengthened from four to five years, the extra year of study being given for the express purpose of clinical work. But, as a matter of fact, the fifth year has become overloaded with

book work intruding upon the practical routine, and reform of some kind is generally felt to be required. The direction which such reform will take must be influenced by the belief or the reverse which is held by the Council in the value of examinations, especially of external examinations, where the students are tested by others than their teachers. It has been suggested that it is the reliance upon external examinations only that makes these tests faulty as well as over-rigorous and it has been proposed by no less an authority than Mr. T. PRIDGIN TEALE, among others, that the different medical schools should examine their own students at any rate in the ancillary sciences. The idea would find favour in Dr. SHAW'S eyes but the Council would probably object to the opening so given for down-grade competition between the schools. Many have insisted that the time has come when all the medical profession should enter through one portal and when two professional examinations only should be necessary before a man can take his place upon the Medical Register. Some educational authorities, taking an exactly opposite view, would have a student's time so divided off that at the end of each year he would be examined in a series of subjects and would not be permitted to go forward with his studies until he had passed such tests in their due order. This means putting a premium on book work and on the employment of "coaches," and we can hardly believe that the General Medical Council is likely to make any alterations in the curriculum that would lead to such a result; but neither can we believe that the Council, all the numberless difficulties being taken into review, is likely, yet at any rate, to look favourably upon the relaxation of the examination system.

Yet the failure of the examination system is to a certain extent proved by several things. The percentage of rejections in medical examinations has steadily increased with the multiplication of examinations; and it is certainly a poor result of education that tests should have so disastrous an outcome. It would seem that the fact of having to get through examinations prevents the students from learning their work from the examination point of view, while depriving them of the time necessary to study from any other point of view. The large part played by the element of chance is a standing argument against the needless increase of examinations. Professor EDGEWORTH, Professor of Political Economy at Oxford, has recorded a number of experiments in the marking of examination papers which have been frequently quoted, as their interest merits. He showed that there are data upon which to found assumptions as to the influence of chance in the results of examinations. In a certain group of examinations he found that the element of chance was such that at any given examination the probability of displacement upon re-examination would amount to one-seventh. When we take into consideration the fact that all candidates for medical examination are not able and not industrious, and that most medical students have now to pass, allowing for subdivisions into subjects, at least six examinations, we can understand how it is that the student's curriculum lasts on the average over six years, although it is only designed by the General Medical Council to cover five years. These facts are only the more suggestive among many, and reflection upon them

been able to check them, are written in a perfectly impartial manner.

Herbert Fry's Royal Guide to the London Charities. Forty-third issue. Edited by JOHN LANE. London: Obatto and Windus. 1907. Pp. 383. Price 1s. 6d. *Classified Directory to the Metropolitan Charities for 1907.* Thirty-second annual edition. Edited by W. F. HOWE. London: Longmans, Green, and Co. 1907. Pp. 214. Price 1s.—These two admirable publications give the would-be alms-giver every information as to how he shall dispose of his charity. The *Classified Directory* issues a table of figures giving the approximate income of the various charities which is most interesting reading. From this table it appears that, including only hospitals, pensions and institutions for the aged, institutions for the supply of food, and institutions for general relief, exclusive of Mansion House funds, the enormous sum of £2,693,362 was collected during the year 1905-06. And yet the daily press is full of harrowing accounts of distress and of appeals for relief, to say nothing of nearly every hospital being in debt or wanting more money. Is distress really so acute or are there waste in, and overlapping of, charitable relief?

JOURNALS AND MAGAZINES.

Annals of Otolaryngology, Rhinology, and Laryngology. December, 1906. *Fraenkel Festschrift* Number.—This number, about three times the usual size of the journal, has been brought out with special reference to the celebration of the jubilee of Professor Fraenkel's connexion with the specialties of rhinology and otology, and it opens with a short article of appreciation in German by Otto Freer. Next follows a review by W. Freudenthal of Fraenkel's life, with a list of his contributions to literature, followed by no less than 53 articles, mostly by well-known Americans, on various diseases of the nose and throat. The first are *Diseases of the Trachea*, by J. E. Newcomb; *Tumours of the Trachea*, by O. F. Theisen; and *Stenosis of the Trachea*, by W. K. Simpson. But the list is too long to quote in *extenso*. There are articles by Logan Turner of Edinburgh, Kelly of Glasgow, and Luc of Paris; *Unilateral Nasal Headache*, by Wingrave of London; *Paraffin Injections*, by Walker Downie; a *Note on Submucous Resection*, by Lake; *Statistical Report on Operations for Sarcoma*, by Price-Brown of Toronto; *Violent Epistaxis in a Gouty Patient*, by Trifiletti of Naples; and *Nasal Operations*, by Baratoux of Paris. These are amongst the contributions from members of the profession residing in various parts of the world. It is a thoroughly representative number and does great credit to the energies of the editors in collecting such a series of papers for such a laudable object as the marking of the great German laryngologist's jubilee in laryngology.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

AN extraordinary Comitia was held on Feb. 22nd, Sir RICHARD DOUGLAS POWELL, Bart., K.C.V.O., the President, being in the chair.

Communications were received from: (1) Mr. S. F. Cowell reporting proceedings of the Council of the Royal College of Surgeons of England on Feb. 7th; and (2) the Mayor of Douglas, inviting the College to send representatives to the Congress of the Royal Institute of Public Health to be held in that town from June 29th to July 5th next.—It was directed that the letter should lie on the table.

Dr. JOHN SHAW wrote resigning his Membership and returning his diploma.—The resignation was accepted.

The REGISTRAR moved, and the SENIOR CENSOR seconded, the enactment of the following temporary by-law:—

That the Licences of the College withdrawn from Mr. Hugh Stanley Revell on Jan. 26th, 1905, under the provisions of By-law cxxxviii., be restored to him, any by-law to the contrary notwithstanding.

This was agreed to, and the PRESIDENT then dissolved the Comitia.

THE REARING OF CHILDREN.

A LECTURE on the rearing of children was delivered by Dr. George Carpenter at the Institute of Hygiene on Feb. 20th. He commenced by remarking that for a child to have a good start in life he should come of healthy parents, free from any taint of alcoholism or of the many diseases that tend to enfeeble the constitution of the offspring. Such fortunate antecedents were seldom attained in actual practice, but in ordinary circumstances much could be effected by carefully safeguarding maternal health during pregnancy.

In regard to the feeding of infants Dr. Carpenter laid stress on the point that proprietary foods should be altogether avoided and that natural feeding whenever possible should be followed in the earlier stages of life. In those cases in which breast feeding was not available, cows' milk diluted with water should be used and in the second year of life undiluted cows' milk would generally be digested well. Dr. Carpenter made a digression to inveigh in strong terms against the unsatisfactory state of the milk-supply and the inadequacy of the powers possessed by local authorities for dealing with unscrupulous dairymen. He pointed out how difficult it was to arouse the public to a sense of the abuses that prevailed in connexion with the supply of milk. Dirt was responsible for the sacrifice of untold numbers of infant lives, while the health and physique of innumerable other children were seriously undermined not only by dirt in milk but by the wholesale supply of tuberculous milk.

After the second year of life it was advisable to feed children on a varied diet, and the lecturer laid down rules as to the nature of food, the quantity to be taken at a meal, and the times of feeding. Maize porridge was recommended and porridge made from oatmeal, which was richer in proteids than either wheat or barley and greatly to be preferred to any of the prepared "oat foods." He was also in favour of giving fruit and fruit juice at an early age, together with milk puddings, but the fruit must be well cooked and free from fibre, skins, and pips. When children were thirsty water should be given invariably and not milk, which should only be given at meals. The water should be properly filtered and if this were not possible it should be boiled. Drinking between meals should be permitted, but the hours of feeding should always be at the same stated times and the stomach should never be overloaded. A child should not be allowed to be capricious in the matter of food but should be trained to eat any wholesome article of diet. If he did not do so there was certain to be some fault on the part of the nurse or parent. As the infant increased in age the diet should become more generous and varied. At the age of two years meat and fish well minced or pounded might be given for dinner and when meat was well digested the mincing might be omitted. Children should be strictly superintended at their meals and they should not be encouraged in any fanciful habits as regards their food. Dr. Carpenter said that bread containing currants, which was much used nowadays, ought not to be given to children as currants were exceedingly indigestible. Simple sweets in moderate quantities were in no respects harmful, but when children were continually eating sweetstuff the natural inference was that their parents were incapable and foolish.

In order to bring up children properly not only wholesome food but plenty of fresh air was necessary. Dr. Carpenter entered into details regarding the position, size, ventilation, and construction of nurseries, and emphasised the points that no gas-stoves should be employed in such apartments, and that the windows should be sufficiently large to admit plenty of sunlight. The question of clothing was dealt with at some length and it was stated that the day nursery should be kept at a temperature between 60° and 65° F. and the night nursery at about 55° F. Dr. Carpenter insisted upon the necessity of children taking exercise and of walking daily out of doors whatever the weather might be. It was pointed out that healthy games were of great value to children for developing the chest, "improving the wind," and making the muscles hard and elastic. Lastly, he commented upon the effect of bathing, clothing, and education upon the health of children and said that many of life's failures were not so much due to heredity as to environment and the neglect of parents and others to do their duty by them when young. On the other hand, many of life's successes were fashioned in the nursery. The importance of early training, therefore, could hardly be over-estimated.

children vaccinated during panic, and at the time when the Government will probably have an insufficient supply of efficient lymph in store. Vaccine lymph does not, as some people may imagine, retain its potency for ever. The President of the Local Government Board has evinced great interest in the subject of infantile mortality and he is now invited to take a step which would have the effect of rendering a large proportion of infants highly susceptible to small-pox. As practically the Minister of Public Health, what will his action be? Those who have urged modification of the existing system are doubtless anxious to see all forms both of compulsion and persuasion swept away. Doubtless whatever Mr. BURNS proposes will, at least in principle, be accepted. Will he select what may appear to be the line of least resistance by striking off from the statute book every trace of compulsion—will he sever the leash which holds back small-pox from the infant population? Such a course would please a small section of the public and would insure the support of certain Members of Parliament holding peculiar views. On the other hand, it is no exaggeration to say that it would literally astound the civilised world which is now tending to follow to its logical conclusion JENNER'S discovery and adopting not only compulsory vaccination but also revaccination. Such a step would be regarded as another of the signs of degeneracy with which the scientific and logical German is wont to associate this country. We shall ourselves be much surprised if Mr. BURNS, in response to sectional clamour, yields thus far. His action, or perhaps inaction, up to the present time we have rather attributed to a desire above everything not to encourage the unfit. We may be wrong but we shall retain our opinion for the present.

In the meantime, suggestions are doubtless reaching the central health office from many quarters and amongst them there has, we believe, been a letter from the National Vaccination Officers' Association urging that certificates of exemption should be issued by these officers who are in effect the local administrators of the Vaccination Acts. These officers suggest that they shall hand the certificate to the parent and retain a copy themselves, entering the name and details in their registers and receiving a registration fee therefor. There is something to be said for the proposal. But if it were carried into effect certain conditions must be attached to it unless, as is possible, it is desired to reduce the whole affair to a farce. If the State believes primary vaccination to be of value as a preventive measure against small-pox during childhood it is surely logical and consistent that it should take some trouble to make its advantages appreciated. If, on the other hand, Mr. BURNS does not, after having studied the evidence for and against the subject, believe that it is of any practical value as a preventive measure, let him sweep the whole organisation connected with it away or turn it to other uses. If he elects to do this he must take such consequences as may eventually accrue. If, on the other hand, he is of opinion that vaccination properly performed protects the infants against small-pox he is morally bound, as the head of the central health department, to diffuse this knowledge. He is not entitled by the responsible position which he occupies to sit on the fence in connexion with a

public health question of this magnitude. Assuming, therefore, that he will seek the advice of scientific men and will follow it, he will, we imagine, arrange that if the duty of issuing certificates of exemption is to be left to the vaccination officer, such officers shall have a greater inducement to procure vaccination than to produce an exemption certificate, that in all cases a fair statement of the value of vaccination shall be presented to the parent and that whoever issues the certificate of exemption shall be furnished with some declaration which shall be read aloud to the applicant before being signed by him. Such declaration, which in our opinion should only be issued by a magistrate, should bring before the parent the seriousness of the step which is being taken and the risks to life which an attack of small-pox would involve to the child in question. If the State elects to provide gratuitous vaccination, it should also through its registrars issue to the parents some simple leaflets setting forth the reasons why the State affords such facilities.

Conversely, if the State, notwithstanding the testimony of science and of Royal Commissions which it has itself appointed, regards vaccination as useless and dangerous, let it diffuse information through its registrars in this sense. Such a step would furnish but another illustration of the fact that science has no active part or parcel in actual administration and that until this condition of affairs is altered and the Local Government Board is reconstituted on an expert basis the public will continue to be debarred from many of the blessings which the researches of science afford. In the event of this latter course being adopted it will be instructive to note whether the country which gave birth to JENNER and set the example of compulsory vaccination to the world will be followed in its degeneracy by a country such as Germany which, by compulsory vaccination and revaccination, has practically banished small-pox and small-pox hospitals from its midst.

Annotations.

"Ne quid nimirum."

LEGISLATION IN REGARD TO BUTTER.

THE Butter and Margarine Bill presented by Sir Edward Strachey, which was ordered by the House of Commons to be printed on Feb. 14th, is intended "to make further provision with respect to the manufacture, importation, and sale of butter and margarine and similar substances." The Bill is calculated to deal the death-blow to the sale of watered butter under the ingenious name of milk-blended butter. It provides for the registration of butter factories in which by way of trade butter is blended, re-worked, or subjected to any other treatment but not so as to cease to be butter. Any premises are similarly to be registered in which there is manufactured any butter substitute (that is to say, any mixture other than margarine, produced by mixing or blending butter with milk, cream, or any substance other than butter) or any imitation butter (that is to say, any article of food which resembles butter, but which is not margarine or a butter substitute) or on which there is carried on the business of a wholesale dealer in butter substitutes or imitation butters. Consignments also of butter substitutes are to be registered

has brought it home to the medical profession that our system of medical education requires considerable reform. We ask too much of the medical student; we do not give him the time in which he can fulfil our demands; we run a risk of killing in him the desire to know anything from first-hand experience or to find out anything for himself; we effect these things by filling him with elaborate and temporary information to assist him in his examinations. These things are beyond controversy, so that Dr SHAW'S earnest words are certain of a sympathetic hearing.

Epidemic Cerebro-Spinal Meningitis: Dr. M. H. Gordon's Memorandum to the Local Government Board.

A REPORT on the micrococcus of epidemic cerebro-spinal meningitis and its identification, presented by Dr. M. H. GORDON to the Local Government Board and recently published, contains a most exhaustive account of the organism and of its relation to the disease. Recent observations on the outbreak of the disease in New York and in Germany have uniformly confirmed the brilliant researches of WEICHSELBAUM made so long ago as 1887, and Dr. GORDON states that at the present time it is generally admitted that the diplococcus intracellularis, or, as it is sometimes called, the meningococcus, is certainly the chief and apparently the sole bacteriological factor in epidemic cerebro-spinal meningitis. The characters of the meningococcus as given in the report are as follows. It is an obligatory aerobic organism failing to grow under anaerobic conditions. In primary cultures it grows best upon agar smeared with blood or upon agar containing ascitic fluid. Dr. GORDON recommends a medium originally devised by WASSERMANN for the gonococcus called nutrose ascitic agar, and he states that the appearance of the colonies of the meningococcus upon this medium affords a means of distinguishing them from those of Gram-positive cocci and even from those of some Gram-negative cocci. They form after 24 hours' growth at 37° C. smooth, moist, grey, translucent circular or oval discs with regular outline. The meningococcus grows in milk but does not produce clotting or any alteration in reaction. It also grows feebly on potato. In order to keep up a stock culture on solid media subculture every two days is necessary. Microscopical examination of preparations of cultures shows that the organism occurs as single cocci, as diplococci in small groups, and occasionally in tetrads. A most important fact in regard to its staining reactions is that it invariably gives a negative result with Gram's stain; another character of great value in differentiating it is that it will not grow at a temperature below 25° C. Observations upon animals, notably those of VON LINGELSHEIM in the recent outbreak in Germany, who observed definite meningitis in monkeys after intraspinal injection of the meningococcus, have definitely established the etiological relationship of this organism to the disease. In regard to the manner of its action no soluble toxin has been found in culture media upon which the meningococcus has been grown, wherefore it would appear that its toxin is

contained within the coccus itself and is therefore an toxin. An agglutinating effect of the serum of patients suffering from the disease upon the organism has been observed and VON LINGELSHEIM in the recent outbreak observed it in 207 cases out of 644 examined. Attempts have been made to utilise this agglutination reaction for the identification of the meningococcus but Dr. GORDON is of opinion that its value for this purpose is small. A further reaction of value in differentiating the organism from other cocci is a fermentation method devised by GORDON; their action upon media containing various sugars, such as glucose, galactose, maltose, and saccharose is studied. The distribution of the organism within the body in cases of the disease and its detection in these various sites are considered in some detail in the report. Lumbar puncture affords the readiest method of obtaining the organism, and its recognition in cultures from the cerebro-spinal fluid is usually easy, since when present it is, as a rule, in pure culture. It can also be obtained from the blood in some cases, and here, again, usually in pure culture. It has been obtained in ten instances out of 41 cases of epidemic cerebro-spinal meningitis examined. A great deal of attention has been devoted to the detection of the organism in the upper respiratory passages, but there the matter presents much greater difficulty owing to the occurrence in the same situation of other cocci showing a negative reaction to Gram's stain, so that according to Dr. GORDON many of the statements made in this connexion are untrustworthy on account of this fact having been overlooked. One of the most important of these organisms likely to be confounded with the meningococcus in cultures made from the upper respiratory passages is the micrococcus catarrhalis, but others are known to exist even in normal saliva. The chief methods recommended for the differentiation of the meningococcus from these other organisms are the characters of its growth on nutrose ascitic agar, its inability to grow on media below 25° C., and its action upon the various carbohydrates. Dr. GORDON'S report is most interesting and affords a very valuable contribution to our knowledge of the organism, while its appearance at the present time is most opportune since it will be of use to those concerned in investigating any cases that may arise.

The Conscientious Objector and the Certificate of Exemption from Vaccination.

THE recent debate in the House of Commons and the undertakings given by Mr. BURNS render it clear that we may shortly expect some modification in the existing procedure for securing certificates of exemption. Although we have for some considerable time held the view that the methods adopted by some magistrates towards those applying for certificates are vexatious and likely to foster opposition, there can, on the other hand, be no question that the wholesale granting of certificates without any regard whatever to the circumstances of each case would be a step the consequences of which we do not fully realise until the advent of smallpox and the rush of the antivaccinationists to have them

stomoxys are recognised to be carriers of a trypanosome disease of horses known in South America as *mal de cadenas*, and inquiries made at the instance of Lieutenant-Colonel Bannerman showed that a species of stomoxys was prevalent in Assam and Bombay. As above mentioned, this insect did not appear to be a carrier of surra. The conveyance of trypanosomiasis becomes an important subject in view of the possible introduction of sleeping sickness into India. The collection of snake venom was continued throughout the year, the dried venom being sent to Kasauli for the manufacture of antivenene. The laboratory snake-man was unfortunately bitten on the left forefinger by a Russell's viper, but was immediately treated by Major G. Lamb, I.M.S., with appropriate antivenene which he had himself made at Kasauli. The result was very gratifying, for the man did not develop any constitutional symptoms of poisoning, although the finger became gangrenous and had to be amputated.

EXPLOSIONS IN SEWERS.

ATTENTION is called by the London County Council to a highly dangerous practice of which motor men appear to be sometimes guilty—namely, that of allowing inflammable naphtha or petrol to escape down the drains. The County Council has issued a timely warning on this subject to persons concerned in the use of petrol. It is pointed out that on several occasions recently explosions have occurred in sewers in which men were working and that life has been lost thereby. The explosions have been traced to the presence of highly inflammable gas in the sewer given off by light petroleum. Under Section 10 of the London County Council (General Powers) Act, 1894, there is an order prohibiting the disposal of inflammable petroleum products in this way, and any offence committed is punishable by a fine not exceeding £20, with an additional fine not exceeding £5 for every day on which the offence continues. In our opinion the fine should be very much heavier considering how very serious the results of such reckless conduct may be. Apart from the danger to life involved, an explosion may rupture the sewer and along its course the result may be a serious pollution of the subsoil.

SUICIDE IN ITALY.

"FOLLOWING up the comments in THE LANCET¹ on 'Suicide and its Methods,'" writes an Italian contributor, "I may now supplement them by the last statistical returns issued on the subject by the Direzione Generale della Statistica. These returns deal with the year 1904 and are full of interest as painful as it is dramatic. Self-murder, it appears, was on the increase in Italy from 1887 to 1893, after which period a slight diminution was noted up to 1903. The cases of suicide in 1887 were 1449, those in 1893 were 2059, while those in 1903 were 1922. But in 1904 the cases amounted to 2166! Of this appalling total, Lombardy contributes the largest number, 337. Next comes Piedmont with 297, the Emilia with 236, Venetia with 224, Tuscany with 210, Sicily with 163, Latium with 132, Liguria with 116, and Campania with 110. In the other provinces of Italy the number of suicides were, in each instance, below 100—the lowest number being in the Basilicata, 19. Classified according to sex, of the 2166 individuals who put themselves to death in 1904 the males numbered 1705 and the females 451. As to the 'stato civile' (condition as citizens), 963 of the suicides were bachelors or spinsters, 893 were married, 250 were in the widowed state, and 55 were of unknown civil condition. The great majority of the suicides occurred between the ages of 20 and 39 years. Between those periods of life the cases

were 877; 700 made away with themselves between the ages of 40 and 50; 380 between 60 and 79; 150 between 15 and 19; 28 at ages above 80; and 12 under ten years old. Touching the means of self-murder employed, that by firearms was the most frequent, numbering 522 cases; drowning was the means in 433 cases; hanging in 388; precipitation from a height in 213; poison in 188; asphyxia in 99; cutting instruments in 68; and crushing under vehicles in 61. As to the mental state of the suicides 'delirio per psicopatia' (frenzy due to psychical causes) figures largely, two under that head being ascribed to alcoholism, ten to the mania consequent on pellagra, and seven to neurasthenia. Of the four seasons the spring was the most prolific in suicide, numbering 640 cases; summer follows with 610, winter with 463, and autumn with 443. The months of April, May, June, and July witnessed the largest number of suicides; October, November, and December the smallest. Classified according to occupation in life the most numerous were those of the agricultural, pastoral, or artisan class, 452. Next, but at a long interval, come the well-to-do (capitalists and such like), numbering 86; and officers (combatant in either service), 77. Of the liberal professions those of the Church and medicine figure least, there being seven among the former and nine among the latter."

NEW VIEWS ON PATHOGENIC MYCOLOGY.

Dr. P. I. Koubassoff (a Russian physician) has set himself the formidable task of disproving the fundamental conceptions of modern mycology and epidemiology.¹ From his observations on malarial and typhoid fever made during a 12 years' stay in Turkestan he concludes that "the life cycle of the pathogenic microbes evolves through the following stages: a growth of the nature of a mycelium sprouts from a hibernating spore, as a bush (*buisson*) from its seed and its diverse constituents (*parties*) develop gradually into a monosporium, a penicillium, an aspergillus, ascospores, bacteriogenic spores, and facultative spores that turn again into hibernating spores, thus resuming the life cycle. The spores, more particularly the hibernating modification, are the real carriers of infection; the microbes, thought specific hitherto, as, e.g., bac. typh. Eberth, are mere 'promycelia.' They are too little resistant to form a pathogenic factor of any degree of importance. Their presence in the blood is possible only after the resistance of the organism has broken down." There is, unfortunately, in the array of observations practically nothing to support these statements. The animal experiments with the microbe of paludism (malaria) and the "microbe of typhoid fever" are little convincing and nothing is done to prove evolution of one of the forms into another by way of culture. Dr. Koubassoff states that he has succeeded in isolating most of the forms described by him from the blood of patients by diluting the blood drawn during the different stages of malaria, typhoid fever, and even pneumonia, with physiological saline solution, and growing them on the following media: Medium I.: To a kilogramme of broth: glycerine, 60.0; peptone, 12.0; ferratin (an iron albuminate), 1.2; glucose, 4.0; and sodium chloride, 4.0. From 7 to 10 per cent. of gelatin is added for a gelatin medium, and for agar from 2 to 3 per cent. of gelatin and 1 per cent. of agar-agar. Medium II.: An entire egg beaten up with a tablespoonful of glycerine and one glass of skimmed milk. On sterilisation this forms a very soft semi-solid medium. The forms thus obtained are identical with forms which were isolated from the green film

¹ THE LANCET, August 4th, 1906, p. 311.

¹ Du Microbe de la Fièvre Typhoïde (Heo-typhus) et de la Théorie Ternaire de Pettenkofer. Des Microbes du Paludisme: Recherches Microbiologiques, Épidémiologiques, et Cliniques. Print by I. N. Kouchneroff, Moscow, 1906. Des Champignons du Paludisme, 1905. Ueber die Pilze des Paludismus, A. Hirschwald, Berlin, 1905.

in the same way as are consignments of margarine in accordance with the provisions of Section 7 of the Sale of Food and Drugs Act, 1899. Any officer of the Board of Agriculture and Fisheries is to have power to enter at all reasonable times premises so registered, and an officer of a local authority who is authorised to procure samples under the Sale of Food and Drugs Acts may have similar powers. When the Board of Agriculture and Fisheries has reason to believe that any of the processes of blending, and so on, are carried on in unregistered premises it may appoint an officer and authorise him to inspect such premises. It is thus proposed to repeal Subsection (2) of Section 7 of the Sale of Food and Drugs Act, 1899. If any substance intended to be used for the adulteration of butter is found in any butter factory the occupier of the factory will be deemed guilty of an offence under this Act and if any oil or fat capable of being so used is found it shall be deemed to be intended to be so used, unless the contrary is proved. This provision is obviously meant to avoid the difficulty which the use of certain oils in butter has created in regard to their detection by chemical analysis. It will be an offence under the Act to store butter or margarine containing more than 16 per cent. of water, or to consign from a factory such butter or margarine unless the occupier or consignor proves that the butter or margarine was not made, blended, or re-worked, or treated in the factory. The sale of any butter substitute containing more than 24 per cent. of water will constitute an offence; and in the list of articles the importation of which is an offence under the Sale of Food and Drugs Act, 1899, butter or margarine containing more than 16 per cent. of water, butter substitutes containing more than 24 per cent. of water, or any imitation butter, except in packages conspicuously marked "butter substitute" or "imitation butter," will be included. Regulations are proposed in regard to the proportion of curd in butter. The fines are commensurate with the offences. Thus for a first offence the fine proposed is £20, for a second offence £50, and for any subsequent offence £100, while imprisonment may be inflicted under Section 17 of the Sale of Food and Drugs Act, 1899, in which such punishment is authorised. We have long pleaded for the more effective control by the State over the sale of butter substitutes. Under the name of milk-blended butter the public have been purchasing for a long time, unwittingly it may be, butter containing a very large proportion of water, and water at 1s. a pound is a somewhat expensive commodity. Again, under the name of butter, substances have been sold mixed largely with foreign oils the chemical characteristics of which are hardly distinguishable by analysis from those of genuine butter fat, and thus the analyst has been rendered helpless to bring fraud to light. We trust, as it is proposed, that this Act will come into operation on the first day of January, 1908, with but little alteration in the principles which it seeks to apply in the interests of the public. We should indeed like to see its provisions put into practice at an even earlier date.

THE SOUTH AFRICAN EXHIBITION.

ON Feb. 22nd there was a private view of the South African Exhibition which is now being held in the Royal Horticultural Hall, Vincent-square, Westminster, and which was formally opened by Their Majesties the King and Queen on Feb. 23rd. A luncheon was given to the invited guests on Feb. 22nd under the chairmanship of Sir Lewis Michell of Rhodesia, at which speeches dealing with the trade prospects of South Africa were made by, among others, the chairman and Mr. O. du P. Ohlappin, the Trade Commissioner for Cape Colony. The four colonies, Cape Colony, Natal, Transvaal and Orange River, and Rhodesia, which make up the British

possessions in South Africa, were all well represented at the exhibition, and as this is the first occasion on which the inhabitants of England have had the opportunity to view specimens of the produce and mineral resources of South Africa gathered together in an orderly manner the result should be widely instructive. Much of what is shown has no concern with a medical journal, but the collections of fruit, vegetables, wheat, barley, and arrowroot promise a great agricultural future for the British South African possessions. If they should be capable, as they are stated to be, of supplying this country with such products of excellent quality and in practically unlimited quantities, the comparative failure, as yet, of the mines will tend to become a matter of secondary importance. At the present time, owing to war and other causes, South Africa has not been able to develop her natural resources as a food-producing country. Now that an era of peace seems to have set in the people of these colonies will have the chance to devote their energies to the cultivation and improvement of the land. This means a good deal, for while there can be little doubt that farmers will find a ready market for much of their produce in this country, they will also be able to feed the resident population at reasonable prices and so to render life in South Africa much cheaper and more attractive.

THE PLAGUE RESEARCH LABORATORY IN BOMBAY.

THE report of the Plague Research Laboratory at Parel, Bombay, for the year ending March 31st, 1906, is an official publication of 30 pages, containing also five full-page plates representing laboratory apparatus. Great part of it is devoted to the subject of Haffkine's plague prophylactic; there are also shorter references to surra, Malta fever, and snake venom. In the introductory part of his report Lieutenant-Colonel W. B. Bannerman, I.M.S., the director of the laboratory, states that from April 1st, 1905, to March 31st, 1906, the number of doses of Haffkine's anti-plague vaccine sent out from the laboratory was 316,639, as against 129,507 for the preceding twelvemonth. Of this total quantity, 219,000 doses were supplied to British India, 50,000 to Native Indian States, and 36,000 to East Africa. The first inoculation with this prophylactic vaccine was performed on Mr. Haffkine himself on Jan. 10th, 1897, and from that time to the end of April, 1906, there have been 6,202,371 doses issued from the laboratory. A full account of the method of bottling the prophylactic, together with illustrations of the apparatus, is given in one of the appendices. All inoculators are now instructed to sterilise their syringes and needles by the hot-oil method before commencing operations, and to re-sterilise the needle between each inoculation so as to obviate any possible chance of contamination. A cheap and portable apparatus which can be used for this purpose in the open air has been introduced and has received the name of "Kapidia's lamp," as Senior Assistant Surgeon R. J. Kapadia worked out the details. A great deal of evidence has been supplied by officers of the Indian Medical Service, medical missionaries, and others showing that there was no impairment of the health of inoculated persons and that the vaccine had a marked prophylactic effect, imparting a high degree of immunity against plague for at least eight or nine months. An outbreak of surra among horses of the mounted police afforded an opportunity of studying this animal disease caused by a trypanosome. The infection was easily kept going through monkeys and guinea-pigs by subcutaneous inoculation, but attempts to do this by means of biting flies of the families tabanus and stomoxys have hitherto failed. Guinea-pigs injected with infected blood lived from 50 to 100 days; monkeys infected with guinea-pigs' blood lived on an average 39.1 days. Flies of the genus

a combination of theobromine-soda with sodium salicylate; barutin, prepared from theobromine, baryta, and sodium salicylate; theophorin, composed of theobromine-soda and formic acid; theobromose, a combination of theobromine and lithium; urocitral, prepared from theobromine-soda and sodium citrate; and uropherin, a compound of theobromine and lithium, with lithium benzoate or salicylate. The following table gives the doses of some of these compounds and their theobromine content.

	Dose.	Percentage of theobromine.
Agurin... ..	15 grains three times a day.	55.1
Barutin	3 to 8 grains frequently.	25.5
Diuretin	7 to 15 " "	59.7
Theophorin	15 grains three times a day.	62.5
Urocitral	7 to 15 grains three times a day.	52.2

Theophorin is the newest of these compounds; experiments on animals have shown that it combines the diuretic properties of theobromine with the tonic properties of sodium formate.

THE DUTTON MEMORIAL.

THE late Dr. Joseph Everett Dutton died, as our readers will remember, at Kasongo, on the Congo, aged 29 years, on Feb. 27th, 1905, from tick fever. Together with his colleague, Dr. J. L. Todd, he contracted the disease while engaged in its study. Both had apparently recovered by Feb. 9th, but Dr. Dutton had a relapse which proved fatal. He had done much excellent work in Africa, and in 1901 had identified the trypanosoma Gambiense, afterwards recognised as the cause of sleeping sickness. It is now proposed to endow a Research Professorship in Tropical Medicine at the Liverpool School of Tropical Medicine as a memorial of Dr. Dutton's life and work. The professorship is to be made a permanency and the income necessary for its maintenance will be supplied by the interest on trust funds. For this object a sum of £10,000 is required. Subscriptions may be sent to Mr. A. H. Milne, Honorary Secretary, Liverpool School of Tropical Medicine, Liverpool. The object is a worthy one and there is no need for us to insist upon the benefits which research into tropical medicine may bring forth. The results already obtained in the cases of malaria and yellow fever are sufficient answer to those who think that money spent on research is wasted.

THE HARVEST OF THE SEA.

FROM the *Fish Trades Gazette* we gather that some discord has arisen amongst the organisations concerned in fishery research over the question of the allotment of Treasury money in aid of this scientific work. It is alleged that the Marine Biological Association of Plymouth has so far alone enjoyed this financial aid which amounts to a considerable sum, and the trade submit that this association is a purely scientific body which is not in touch with either the trade or the various bodies concerned with fishery legislation and administration. A week or so ago a deputation from the Lancashire and Western Sea Fishery Committee (whose excellent work was referred to in a leading article in THE LANCET of Feb. 2nd) waited upon the Chancellor of the Exchequer at the House of Commons with a view of soliciting assistance from the Treasury in aid of its scientific work. It appears that the Lancashire organisation has supported its own researches out of the local rates, and at the same time the members have contributed to the cost of researches on the East and South Coasts by means of taxes. It was now thought that any Treasury grant should not be possible body but directly to the central

fishery authority—viz., the Board of Agriculture and Fisheries. In a conciliatory reply Mr. Asquith said that he had come very definitely to the conclusion that the time had arrived for a thorough investigation of the whole question by an independent and a competent authority. Whatever financial arrangements were made during the present year would be of a strictly provisional kind and it was his intention to bring together as soon as possible by means of an inquiry all the various sources of information which were available in order to see if some definite scheme could not be arranged to coördinate local and general effort on this most important economic question. We can hardly think that the members of the trade are foolish enough to underrate the value of scientific work, but, of course, on the great questions at issue it is important that practical results should sooner or later be forthcoming. It is to be hoped that all sides will agree on this matter and heartily coöperate in the great work in hand, the consummation of which is to bring good to all concerned. We have no doubt that the Chancellor of the Exchequer will not be long in arriving at an equitable scheme by which research will be encouraged and supported in a broad direction.

INFANT LIFE PROTECTION.

A BILL to amend the Infant Life Protection Act of 1897 has been introduced into the House of Commons by Mr. Staveley Hill, supported by, amongst others, Sir John Kenna-way and Mr. Ramsay Macdonald. The Act of 1897 dealt with nurse children under five years of age only in cases where more than one was taken by the baby farmer, or in the case of a child under two years of age only where a sum of money not exceeding £20 was paid down. Furthermore, the local authority could only remove the child from the baby farmer's premises if the said child's health were endangered either by reason of the house being insanitary or the person who had the child in his or her care being ignorant or negligent. The object of the new Bill is, amongst others, to extend the provisions of the Act to cases where only one child is taken in to be nursed or maintained and to any child received in consideration of a sum of money paid down, whatever the amount may be; to raise to seven years the age limit of children within the Act; to enable the local authority to remove an infant kept by a person who is unfit by reason of character or otherwise to have his or her care and maintenance, or who is in a house or premises unsuitable for the purpose, although such person or premises are not so unfit as to endanger the child's health; and to require notice to be given of all changes of residence of a person having the care or custody of children within the Act under penalty of imprisonment or fine. We are quite in sympathy with the objects of this Bill, especially in so far as it applies to cases where only one child is taken or to cases in which any sum of money is paid down. With regard to the question of the local authority removing children from unsuitable houses this in many instances will be a much needed reform but we do not envy the local authority its task of deciding whether or not a house or person is unsuitable from a moral point of view.

A MEDICAL INFORMATION OFFICE IN BERLIN.

FOR some years an office at which medical information as to hospitals, lectures, and other subjects of interest to medical men can be obtained has been at work in Paris, and a full description of it appeared in THE LANCET of Jan. 17th, 1903, p. 207. We now learn that a somewhat similar institution is about to be opened in Berlin at the Kaiserin Friedrich-Haus (Luisenplatz 2-4). The aim of the institution is to assist foreign physicians who go to Berlin to study. Information is to be given regarding all lectures,

in stagnant waters, cesspools, marshes, and so on. In their present state the publications add nothing to that part of science which they are meant to revolutionise, in spite of the numerous excellent microphotographs.

THE DEATH OF HENRI MOISSAN.

DEATH would appear to be ruthlessly active in the ranks of chemical science. Curie, Mendeléeff, and Menshutkin have been taken away comparatively recently, and now the scientific world is the poorer for the loss of M. Henri Moissan, the first to isolate fluorine in the free state and the first also to produce artificial diamonds on any scale. M. Moissan was 54 years of age and he died on Feb. 20th after having undergone an operation for appendicitis. It was in 1886 that M. Moissan succeeded in isolating fluorine by the electrolysis of fluoride in a platinum tube closed with stoppers of fluor spar. Fluorine proved to be a pale green gas which has a powerful action on almost all known substances. In 1906 M. Moissan was awarded the Nobel prize in acknowledgment of the remarkable results which he obtained in his high-temperature experiments, using for the purpose the intense heat of the electric arc. These experiments led the way to the commercial production of calcium carbide (and thus indirectly of the marvellous illuminating gas acetylene), aluminium, and metallic calcium. The temperature reached was oftentimes near to 7000° F. M. Moissan by means of this intense heat fused iron together with carbon and then suddenly cooled the mass. The effect produced enormous pressure within, the outer part solidifying, and on fracturing the solid material it was found that part of the carbon had crystallised into diamonds. They were microscopic in size but still they were undoubtedly diamonds. Similar crystals are occasionally found in the steel and slag produced in the furnaces of iron foundries. M. Moissan was a most indefatigable worker in the field of chemical research, a fact which gained for chemistry some new and valuable results and his death at a comparatively early age will very generally be regretted.

ANKYLOSTOMIASIS IN BELGIUM.

Consul-General Sir Cecil Hertslet has issued a most interesting report¹ upon ankylostomiasis and the means taken to combat this disease in Belgium. The report opens with a brief account of the nature of the disease and of the manner of its spread and then goes on to detail the steps which the Belgian Government took to combat the evil. About three years ago a commission was appointed which reported that in the Liège district alone some 25 per cent. of the miners were infected. In November, 1904, a Royal decree promulgated certain rules for the district of Liège. The mines were divided into two classes, those infected and those not infected or at least which were considered to be only lightly infected and which should be able to furnish a clean bill of health within six months from the passing of the decree. In this latter class notification of any case of ankylostomiasis was required. With regard to the former class proper closet accommodation of at least one closet for every 25 workers had to be provided at the pit's mouth and buckets with watertight linings and tight-fitting covers had to be provided for below ground. Stringent rules were drawn up for the keeping of both closets and buckets clean. All miners undergo a clinical and bacteriological examination. If found infected they are not to work. While off work, however, they are paid a sum amounting to about 17s. per week, which is provided partly by the provincial authorities and partly by the mine-owners. Cards containing simple rules of hygiene were issued to

miners, but these rules, says Sir Cecil Hertslet, though good in theory, were in practice found to be somewhat impracticable. Other cards were issued to mine-owners. As regards treatment, the drugs chiefly used were male fern, salicylic acid, and eucalyptus with castor oil. Of these three mixtures that containing eucalyptus seems most popular and quite as efficacious as the others. As a result of these measures the following figures show very well the progress made in the fight against the disease. In 1902 in 16 mines in the province of Liège the percentage of miners affected was 29·5; in 1904 it was only 12·25. By the beginning of this year five of the mines were reported as free from the disease. Although the law was at first made applicable to the province of Liège only it has now been applied to the province of Hainaut also.

HALTING PLACES FOR THE MOTOR OMNIBUS.

SOME years ago we suggested in these columns that many accidents in the street might be avoided if the omnibuses had definite stopping places along the route, besides which the labour and strain of pulling up and re-starting the horses would be minimised. Out of kindness and consideration for the horses not a few persons have sustained an unpleasant, if not serious, accident by refusing to have the omnibus "pulled up" when they wished to dismount; others have had no consideration at all and have consequently always alighted in safety. There is no reason why anybody should be exposed to the risk entailed by jumping on or off an omnibus while it is in motion. If there were definite calling places no such risk would be involved at all. If this is the case with the horse-drawn omnibus, how much more so is it with the motor omnibus. It is, in fact, only the absolutely sturdy person, sound in nerve, wind, and limb, who dares to jump on or off a motor omnibus while it is careering along. The pace of these vehicles renders it a highly dangerous proceeding for almost anyone to attempt to alight from them whilst in motion, and an attempt to jump on is just as likely to result in an accident. We are aware that there are places in the streets where by some unwritten law omnibuses are required to stop but as a rule these stations are too far apart and too irregular to be generally useful, and even then it is not everybody—and certainly it is not strangers in the metropolis—who know of their existence. As a matter of fact, these halting places do not exist for the convenience of the public as patrons of the omnibus, but merely so that the traffic at busy corners and crossings shall not be impeded by these vehicles stopping there. The system which we suggest is in vogue on most tramways and now that the motor omnibus is as fast as the electric tramcar it should be subjected, it seems to us, to the same regulations for the convenience and safety of the public.

THE THEOBROMINE CLASS OF DIURETICS.

Dr. F. Zernik, who has contributed largely to our knowledge of the composition of proprietary medicines, has published in the *Apotheker Zeitung*, 1906, p. 898, the results of his analysis of the various theobromine derivatives which have been placed before the profession as diuretics. Theobromine itself has been recommended as a diuretic; it is considered superior to caffeine owing to its relatively slight action on the central nervous system. Theobromine is only slightly soluble in water; it forms a soluble compound with sodium hydroxide, having so marked an alkaline reaction that it is not suitable for therapeutic use. Hence various attempts have been made to produce soluble compounds of theobromine suitable for administration. These include agurin, a compound of theobromine-soda and sodium acetate; diuretin,

¹ Report on the Precautions Taken to Combat Ankylostomiasis (Miners' Worm Disease) in Belgium. No. 656 Miscellaneous Series of Diplomatic and Consular Reports published by the Foreign Office.

to pepsin. Pepsin is completely destroyed by trypsin in alkaline solution and almost entirely so by 0.01 per cent. of sodium hydroxide. Diastase is rendered inactive in nine hours by 0.1 per cent. of sodium hydroxide, it is almost entirely destroyed by 0.009 per cent. of hydrochloric acid—i.e., in a solution containing one-twentieth the acidity of the gastric juice—and its activity is weakened by pepsin even in neutral solution. But diastase is not affected by trypsin, rennin is not destroyed by pepsin, and invertin is not injured by pepsin, trypsin, or diastase. These laboratory results will doubtless give such therapeutic monstrosities their quietus. There is no place in medicine for them. One of these preparations is said to contain "the five active agents of digestion, pepsin, 'veg.' (sic) ptyalin, pancreatin, lactic and hydrochloric acids," and it is stated to be "superior to all other remedies in dyspepsia and diseases arising from imperfect digestion." But on examination it was not possible to establish the presence of either the proteolytic or the amylolytic ferment. Another elixir—"the only true digestant, because it contains the enzymes of all the glands which are necessary for digestion"—was found to possess no enzyme activity whatever.

AN INTERNATIONAL CONGRESS ON PSYCHIATRY, NEUROLOGY, PSYCHOLOGY, AND THE NURSING OF LUNATICS.

A CONGRESS under this comprehensive title will be held at Amsterdam from Sept. 2nd to 7th, 1907. The congress is under the patronage of Queen Wilhelmina and Prince Hendrik of the Netherlands, and the honorary presidents are the Dutch Minister for Home Affairs, the Minister of Justice, the Commissary of the Queen in the province of North Holland, and the Burgomaster of Amsterdam. Dr. G. Jellgersma, professor of psychiatry and neurology at the University of Leyden, is the president, and Dr. W. P. Ruijsch, chief inspector of public health at the Hague, is the vice-president. There are a large "Propaganda Committee for the Netherlands" and a widely distributed "International Propaganda Committee." The congress will consist of four sections: (1) Psychiatry and Neurology (President, Dr. O. Winkler of Amsterdam); (2) Psychology and Psycho-physics (President, Dr. G. Heijmans of Groningen); (3) Nursing of Lunatics (President, Dr. W. P. Ruijsch of the Hague); and (4) Exhibition (President, Dr. J. van Deventer, senior, of Amsterdam). The congress will consist of general sessions and meetings of sections. In the general sessions chosen subjects will be dealt with by specially invited speakers. At the meetings of sections special questions will be discussed and criticism will be invited. Any one taking an interest in the subjects of the congress may become a member thereof. The languages employed will be English, French, and German. Members who will treat any suitable subject are requested to send a synopsis before May 1st to the secretary, who will see to the translation, printing, and distribution thereof. Those wishing to attend the congress are requested to sign a special card which will be sent by the secretary and to return it with their visiting card and cheque for 16s. 8d. to him. Tickets admitting ladies accompanying members may be obtained at 8s. 4d. each. A more detailed programme will be issued shortly. The general secretary is Dr. G. A. M. van Wayenburg, Prinsegracht, 717, Amsterdam.

EPIDEMIC DIARRHŒA IN GORTON.

Mr. A. W. Martin, the medical officer of health of the urban district of Gorton, in a special report to the Local Government Board on the prevalence of diarrhœa in that district during the summer and autumn months of 1906, states that from July 13th to Oct. 25th there were 75 registered deaths from diarrhœa, 38 being males and 37 females.

Of these deaths 54 were in children under 12 months of age and 67 out of the total 75 were under two years of age. Of the 54 deaths of children under one year of age 42 were bottle-fed. Four had been breast-fed, but when taken ill were having other food. Five were exclusively breast-fed and in three cases no information could be obtained. Of the 51 deaths concerning which information was obtainable, 35 mothers had attempted breast-feeding and 26 of these had failed, while only nine had been able to suckle their children for the full term. Of the total 75 deaths 60 occurred in houses supplied with privy middens and 15 in those supplied with water-closets, the rate per 1000 being 15 deaths per 1000 privies and 3.8 per 1000 water-closets. These figures show that two factors are principally concerned in the spread of the disease. The one, of course, is the privy midden system and the other the absence of breast feeding. Mr. Martin considers that "the present generation is witnessing an occurrence in the evolution of man probably never experienced by the human race previously, and that is a race of breastless women." That organs unused to atrophy is a canon of physiology, and it may be that the disinclination or inability of the modern woman to suckle her child, the inability being from social conditions, is leading to a real inability from atrophy of the mammary glands. To this cause may be due the enormous number of quack advertisements which disfigure the pages of popular magazines and which pretend to offer nostrums able to increase the size of the mammary glands. Whatever be the cause, the question of how children are to be breast-fed is one which demands the most serious attention of those concerned for the progress of the country, and although the matter is being taken in hand in many places a true solution of the problem seems as yet far distant.

THE Society of Tropical Medicine and Hygiene was formed on Jan. 4th of this year at a meeting held at the Colonial Office for the purpose of the study and discussion of diseases met with in tropical countries. The second meeting of the society will be held on Friday, March 15th, at 5.30 P.M., at the Royal College of Physicians of London, to consider the rules drawn up by a sub-committee for the constitution of the society and the regulation of its work. So much has been done in recent years to advance the knowledge of the diseases of warm climates that there must be ample food for discussion and study in this branch of medicine, and the meetings of the society should prove interesting not only to medical men with tropical experience but to every medical man engaged in the practice of medicine wherever his lot may be cast.

At a meeting of the Harveian Society of London on Thursday, March 7th, at 8.30 P.M., Mr. W. Watson Oheyne, F.R.S., will open a discussion on the Diagnosis and Treatment of Fractures in the Neighbourhood of a Joint, and will illustrate his remarks with skiagraphs. The following have promised to speak: Professor Howard Marsh, Mr. Edmund Owen, Mr. A. Pearce Gould, Mr. W. Arbuthnot Lane, Mr. Robert Jones (Liverpool), and Mr. J. Lynn Thomas (Cardiff). Members of the medical profession are invited to be present.

WE are informed that Dr. J. Kingston Fowler and Dr. J. Rose Bradford have consented to stand for re-election as representatives of the Faculty of Medicine upon the Senate of the University of London.

THE Department of Public Health of Queensland, in a bulletin dated Jan. 5th, states that for the week ending on that date one case of bubonic plague occurred. The patient was a male, aged 17 years. A further bulletin, dated Jan. 12th, states that no other case had occurred. As

both those to which admission is free and those for admission to which a fee is charged. Particulars can also be obtained as to hospitals and other medical institutions, and at what times and under what conditions they may be visited. Finally, information can be obtained as to lectures at the various clinics or medical societies and as to opportunities for watching operations in both clinics and hospitals. All information will be given free of charge. We are glad to be able to lay this information before our readers and we owe it to the courtesy of Professor Dr. Kutner, the director of the Kaiserin Friedrich-Haus, that we are able to do so. The new Information Office, however, is not the first of the kind in Berlin, for a similar one was opened in connexion with the University at the commencement of 1905 and a note upon it from our Berlin correspondent appeared in THE LANCET of Jan. 14th of that year. Such institutions as the Paris Bureau de Renseignements Médicaux, and that already existing and that about to be opened in Berlin, are essential to any medical man desirous of studying in a foreign town if he is not to waste a large portion of the time which he can afford to devote to study away from home, and such period is often very limited.

THE PERCENTAGE OF PHOSPHORUS IN VARIOUS FOODS.

M. Baland has published in the *Journal de Pharmacie et de Chimie* for January a series of determinations of the amount of phosphorus present in various foodstuffs. The determinations were made on the actual food and not on the ash obtained by their ignition. The percentages of phosphorus, expressed as phosphorus pentoxide (P_2O_5), are as follows: Wheat (except Australian wheat) and oats, 0.65 to 1.11; maize, millet, barley, and rice, up to 0.8; carrots, cabbages, turnips, and onions, 0.1; asparagus ends, cauliflower, lettuce, and leeks, 0.18; potatoes, 0.29; truffles, 0.5; peas, 0.6 to 1.0; haricot beans and lentils, to 1.35; beans, 1.45; cherries, currants, strawberries, oranges, pears, and grapes, to 0.1; dried figs, dates, and bananas, to 0.3; almonds and dried nuts, to 0.9; beef, veal, mutton, and fowl, to 0.45; fish, to 0.6; snails, oysters, and mussels, 0.26 to 0.35; cheese—Gruyère 1.81, Dutch 1.62, Camembert 1.1, average 0.68 to 1.81; roasted coffee, 0.4; cocoa, to 1.3; chocolate and milk (beverage), 0.62; hen's eggs, 0.26; white of egg, 0.015; butter, 0.13; and cod-liver oil, 0.05. M. Baland deplores the craze for fine white flour. Year by year in response to the demand of the consumer, machinery is perfected for producing still finer flour, containing, as a consequence, still less phosphorus and nitrogen.

HENRY VIII.'S BARBER.

THE origin of Saturday night tubbing seems to be lost in the mists of antiquity. According to Mr. Sidney Young, F.S.A., author of the "Annals of the Barber Surgeons," who on Feb. 23rd delivered a most erudite and amusing discourse at Barbers' Hall on the Relations Anciently Existing between Barbers and Surgeons, it was the custom of no less a person than King Henry VIII. to perform partial ablutions on occasional Saturday evenings. The "King's barber," one John Pen, Penn, or Penne, an ancestor of the famous Quaker of that name, was expected to be present at these august ceremonies, when the Defender of the Faith was pleased "to cleanse his head, legs, or feet." The regulation requiring the barber's attendance was a standing order, dating apparently from the reign of Edward IV. It is preserved in the "Liber Niger Domus Regis" (Harl. MS., 642), and its wording seems to imply that the solemn washings were partial and special rather than thorough, and that the king's

majesty often did without them. The royal barber, who was also a groom of the privy chamber and one of the 15 persons allowed to enter it, was also required to shave the king daily, "having in readiness his water, basons, knives, combs, scissours, and such other stuffe as to his roome doth appertaine for trimming and dressing of the king's head and beard." He was further required to "take a special regard to the pure and clean keeping of his own person and apparel, using himself always honestly in his conversation without resorting to the company of vile persons," and so on. Thus we have the beginnings of asepsis. When he was shaving the king a knight of the chamber or squire of the body, or both, were required to be present in order to prevent foul play. The portrait of Pen figures prominently in Holbein's famous picture of Henry VIII. delivering a charter to the barbers and surgeons on the occasion of their union in one body. The face is so fine in itself and so well painted that the great Sir Robert Peel was said to have offered the Barbers' Corporation £2000 if it would allow him to have it cut out and replaced by a copy. He is further reported to have said that he should like to sleep on the Barbers' dining table and to gaze on awakening at his favourite Pen. The table, as its form plainly shows, is an ancient dissecting table, whither were carried the corpses of malefactors handed over at Tyburn before 1745 to the barber-surgeons. There can be no doubt about the use to which the table was put, but, as Mr. Sidney Young informed his hearers, the anecdote touching Sir Robert Peel is pure myth.

EPIDEMIC CEREBRO-SPINAL FEVER.

THE epidemic of cerebro-spinal fever continues to make steady progress. Two cases have now occurred in London during the present week, one in Stepney and one in University College Hospital, the last-mentioned patient being a man, aged 28 years, who was admitted on Feb. 19th and died on the 25th. The source of his infection has not been traced and there are not as yet any signs of an extension of the disease from this centre. In Glasgow 14 fresh cases were notified and 17 deaths occurred on Feb. 24th, 25th, and 26th. Up to the present time there have been 248 cases in Glasgow with 142 deaths. In Belfast six cases were notified on Feb. 22nd and five deaths occurred on Feb. 25th and 26th; according to the latest returns there have been in all 118 cases with 71 deaths. In Dublin one fresh case was notified on Feb. 26th, making the eleventh in that city; there have been eight deaths, and three patients remain under treatment. In England fresh cases of the disease have been found in Leicester, Gravesend, Obelmsford, and Handsworth. In Scotland isolated cases have occurred in Borrowstounness, Kilsyth, Grangeopans, Loanhead, and Peebles. In Ireland there have also been isolated cases at Greencastle, Ballymoney, Newry, and Sheeptown.

THE WORTHLESSNESS OF LIQUID PREPARATIONS CONTAINING MORE THAN ONE DIGESTIVE FERMENT.

LIQUID preparations containing more than one digestive ferment—e.g., pancreatin (trypsin) and pepsin—have recently been put before the profession without regard to the fact that the ferments are mutually incompatible in solution. The worthlessness of such preparations has been proved by Dr. Torald Sollmann and emphasised in a special report of the Council on Pharmacy and Chemistry of the American Medical Association, which was published in the *Journal of the American Medical Association* of Feb. 2nd. Dr. Sollmann has found that trypsin is destroyed in six hours at 40°C. in a solution containing 0.56 per cent. of hydrochloric acid without pepsin, or 0.112 per cent. hydrochloric acid in addition

The first month past, the causes just specified become rapidly less fatal, but in their stead bronchitis, pneumonia, whooping-cough, and diarrhoeal disorders become conspicuous in the death roll. Bronchitis destroys the largest number of victims in the second month of life, whilst pneumonia is most destructive in the later months of the first year. Among common infectious diseases the most fatal in early infancy are whooping-cough and measles; the former disease shows almost uniformly high fatality from the second to the end of the twelfth month and then rapidly declines, whereas the latter disease attains its maximum fatality in the second year and thereafter becomes considerably less fatal.

(To be concluded.)

MEDICINE AND THE LAW.

The Action of the Police at Manchester in a Case of Attempted Suicide.

IN THE LANCET of Feb. 16th, p. 466, an account was given of the prosecution by the police at Manchester of a medical man and two others for an assault alleged to have been committed in resisting the police in the fulfilment of their duty. An elderly man had attempted to commit suicide by cutting his throat and the relatives had communicated with the police in addition to summoning medical assistance. The police were apparently under the impression that an attempt at suicide of this kind was a serious crime demanding summary arrest and the close custody and observation of the criminal, and having made up their mind that he must be removed to the Ancoats Hospital proceeded to carry out their resolution in spite of the protests of the relatives and in the teeth of a warning from Mr. S. Bagley, the medical practitioner who was already in attendance, that such a course would be attended with danger to the patient. In opposing the removal Mr. Bagley and the patient's two sons offered sufficient resistance to form the basis of a charge, and although the "assault" involved was not more than what is generally termed "technical," the police were ill-advised enough to make it the subject of legal proceedings. The charge was dismissed after an argument at least as technical as the alleged assault, on the ground that attempted suicide being a misdemeanour only the police could not arrest without a warrant unless they had witnessed the commission of the act, and that consequently to resist them did not constitute an offence. It was, however, contended on behalf of the prosecution that under a special Act passed for the benefit of Manchester in 1844 its police possess powers not enjoyed by similar officials outside the scope of that Act, and upon this question an application was made to have a case stated for the consideration of the High Court. Apart from this point, of interest chiefly to the citizens of Manchester and its police, the case appears to involve little else but the consideration of the conduct of those responsible for the arrest in question. This is a matter to which their superior officers may well give attention. To remove a wounded person, whatever his offence, when a medical man expresses the opinion that he should remain where he is, is a dangerous course to adopt. Should the death of the prisoner result from the removal the police officer responsible might find a very ugly charge framed against himself. The attempt at suicide is not now treated by the law as seriously as it was only a few years ago, when trial upon indictment necessarily followed, so that the great anxiety shown in this case to effect an immediate arrest was unusual. A point of importance to which the attention of the police should also be drawn is this: the relatives appear to have wished the old man to remain at home and to be treated there with a police officer in charge of him, and the medical man considered that this could be done. In other words, he appears to have been a patient who if he had received an injury of the same character accidentally would have been treated for it at home. Why, then, should the police take him to a hospital at all? A hospital, apart from such emergencies as street accidents, is a charitable institution for the benefit of those whose cases cannot be dealt with in their homes and who cannot afford to pay for treatment elsewhere. If the patient is a prisoner he is still received in the hospital, for it opens its doors to all without distinction of religious creed or of moral character. This, however, affords no justification for

the police filling a bed in a hospital ward with a prisoner for their own convenience and without regard as to whether he is a proper object of the hospital's charity or not. It is to be hoped that this aspect of the case will be brought to the notice of the Manchester police, and that the protests of Mr. Bagley will have had the effect of causing them to act with more care and consideration in future. He doubtless regrets that owing to the case against him having been dismissed upon a point of law he was not called upon to justify his action by his evidence and to put forward his version of the incidents of which the police had given theirs.

Two American Suits: Pressure Paralysis as an Accident, and Expectancy of Life.

It is not uncommon to find that more or less prolonged pressure upon a nerve trunk will result in the temporary paralysis of the muscles and anesthesia of the skin surfaces which are supplied by that nerve. The familiar instance is "crutch palsy" of the upper extremity. Syphilitic perioritis may lead to a gradual effect of a similar nature when, for instance, a nerve trunk passes through a foramen the walls of which are inflamed. Sometimes after a somewhat lengthy operation, where the anaesthetised patient has had to lie in a strained or unnatural posture, the paralysis which may result may puzzle one clinically inexperienced in such cases. Lately in the Indiana (U.S.A.) courts such a case led to legal proceedings. It was held that an injury to the hand superinduced by numbness resulting from using it and the forearm as a head-rest during sleep was covered by insurance against injuries through external and accidental means. The case is cited as *The Aetna Life Insurance Co. v. Fitzgerald*.—There are certain matters which, by the policy of the law, are excluded from discussion as being so problematical and so impossible of decision that it is merely to waste the court's time and to foster perjury to admit their forensic consideration. Such a matter might appear to be the probable expectancy of a person's life in the light of the knowledge of the age at death of his parents and grandparents. But it will be recalled that life insurance offices make such matters the subject of pertinent questions and the replies have been found to guide such offices in the estimation of the "life" under consideration. In the case of *Haynes v. Watervale Railway*, recently tried in the State of Maine, it was held that evidence of the age of the parents of the plaintiff was to be allowed in forming an estimate of the expectancy of his own life.

The Case of an East-End Bakery.

Two years ago, on Feb. 6th, 1905, a journeyman baker in the East-End fell down while at work and died shortly afterwards and the jury at the inquest upon his body found a verdict in accordance with medical evidence to the effect that death was due to heart failure accelerated by long hours of labour.¹ The *Daily Express* gave prominence to a somewhat sensational account of the case and published comment upon it couched in strong terms, upon which the master baker brought an action for libel. In defence the *Daily Express* pleaded that the words complained of were in their natural and ordinary meaning true in substance and in fact, and the jury took this view to the extent that although they found a verdict for the plaintiff they awarded him only one farthing as damages. Appeals by defendants against verdicts upon the grounds that the damages awarded are excessive are common, but it is unusual for appeals to come from plaintiffs who consider the damages inadequate. The baker plaintiff, however, appealed in this case successfully so far as the Court of Appeal was concerned, Lords Justices Vaughan Williams and Stirling considering him entitled to a new trial. Lord Justice Fletcher Moulton dissented and the House of Lords has now declared that he was right and the order for a new trial has been reversed. The late Lord Davey summed up the law by saying that the practice was not to disturb a verdict unless it was "perverse," and that in the case before their lordships it could not be said that the verdict was not one that might reasonably have been arrived at. The *Daily Express* is to be congratulated upon its success in a case of great importance to newspapers which, when commenting in outspoken fashion and in accordance with their duty upon matters in which the public health and public welfare are concerned, may fall into some trifling error of detail. There are people who may complain of such an error but who may not deserve

regards the Mauritius a telegram from the Governor received at the Colonial Office on Feb. 22nd states that for the week ending Feb. 21st there were eight cases of bubonic plague and six deaths from the disease.

THE REGISTRAR-GENERAL'S SIXTY-EIGHTH ANNUAL REPORT.

II.¹

In a previous notice of this report we summarised the weighty remarks of the Registrar-General on the waning fertility of English mothers. The causes of this calamity were discussed, as were also its effects in modifying the age-constitution of the population and thus seriously affecting the rate of mortality.

Our readers may remember that in commenting on that portion of the report of the Duke of Devonshire's Committee on Physical Deterioration which advocates the establishment in this country of a system of disease registration, we strongly urged the desirability of the project on the ground that, valuable as the national mortality returns undoubtedly are, they can never fully supply the place of a record of that sickness which results fatally in usually a small, and always an uncertain, portion of the cases occurring. We are, therefore, the more gratified to find that the official upon whom would probably devolve the duty of administering such a system in the event of its establishment cordially supports the recommendation to which we have referred. "Ever since the establishment of the General Register Office," writes Sir William Dunbar, "the only available test by which the state of the public health could be judged has been the mortality prevailing locally from time to time. It is, however, difficult to avoid the conclusion that the data which, for more than a half century, have been relied on for this purpose—relating as they do solely to sickness of sufficient intensity to destroy life—form no reliable measure of the aggregate loss of health and of 'earning power' experienced by the community as the result of sickness. Of the 'sickness' that is not unto death' the mere statement of the resulting mortality forms but a rough indication; for the fatality of most diseases varies enormously, both in different places and in different times. Not many years ago the truth of this contention was recognised by Parliament when one of the more enlightened English municipalities obtained legal powers for the notification of certain infectious diseases the prevalence of which was known to be prejudicial to health and life. Among diseases other than the common infectious ailments now recognised as communicable are tuberculosis and pneumonia, which diseases alone destroy more lives annually than do all the common infectious diseases put together. Regarding the quantitative incidence of tuberculosis or of pneumonia, not to speak of several other prevalent and fatal diseases, we are at present ignorant. A large portion of the sufferers from these diseases come under the treatment of the public hospitals, infirmaries, and dispensaries, and in view of the desirability of obtaining accurate information on this point it is, in my judgment, desirable that an attempt should be made to give effect to the recommendation of the Duke of Devonshire's Committee on Physical Deterioration by collecting periodical returns of sickness from the Poor-law medical officers in coöperation with the hospitals and other charitable institutions throughout the country." We quote Sir William Dunbar thus liberally in order to show that he is in sympathy with the recommendation of the committee referred to, and also, we may add, with ourselves. The Registrar-General does not specify the department with which the decision rests, whether the Local Government Board or the General Register Office; but we gather from his remarks that in the event of a beginning being decided upon no difficulties will be raised by his department.

As in previous reports, the general subject of mortality is treated of in Dr. Tatham's letter to the Registrar-General. From this letter we learn that in the year 1905 the loss of life by disease in England and Wales was less than in any previous year on record. As compared with the average rates in the previous five years the mortality among both males and females, in town as well as in country,

showed a substantial reduction, the fall in the urban group of counties being considerably greater than in the rural. In view of the steadily growing interest attaching to infantile mortality great prominence is given to the subject in the present report. In the volume for the previous year a new table had been given showing the loss of life among infants in groups of months within the first year after birth, and in each successive year of the first five. That table has been greatly extended for the present report, in fact, it has been partially reconstructed, so as still further to subdivide the first year of life, the deaths from the principal causes being shown in terms of 1000 births, in each week of the first month, and in each month of the first year. The death-rates are also shown of survivors in each subsequent year of the first quinquennium of life. This tabular extension has involved the re-abstraction of the whole of the infant deaths in 1905, but Dr. Tatham is confident that the additional labour has been justified by the results, more especially since the table now corresponds in all respects to the new tabular form No. V. issued to medical officers of health by the Local Government Board. Moreover, inasmuch as infantile mortality is shown in the present report for representative areas, urban as well as rural, medical officers of health will possess in these tables trustworthy standards by which the infantile mortality of their own districts may be judged.

In the pages of THE LANCET attention has frequently been directed to the fact that although the general mortality in this country has steadily fallen in the course of the last half century, nevertheless this benefit has by no means been shared by infants in their first year of life. Frequent and at times considerable fluctuations in the rate of death among young children are caused by atmospheric and seasonal conditions, but if an average of several years be taken it will be found that infants in their first year of life perish as rapidly now as they did half a century ago. Although this fact has been steadily kept before us in the successive reports of the Registrar-General it is only in comparatively recent times that public interest has been thoroughly aroused. Last June, however, a conference on the subject was called by Mr. John Burns, President of the Local Government Board, and the medical officer of that Board has promptly taken steps to procure periodically from every medical officer of health in England and Wales a return of mortality in the infantile community of his district.

We observe that the mortality in specified parts of the first year of life is indicated as a proportion of the total births registered within the year, although the more correct method would have been to calculate the deaths in each part of the first year on the number of survivors or on the mean population of the period. Inasmuch, however, as the births are not at present returned for intervals of time shorter than three months it is not possible to calculate precisely the number of survivors at the several weeks or months of the first year. For these periods it is explained that the published figures must be regarded as records of that portion of the total mortality under one year that occurs in the successive weeks or months of that period rather than as death-rates in the ordinary acceptance of that term.

It is shown in the tables that about one-fifth part of the total loss of life in the first year takes place within the first week after birth, whilst by the end of the first month the proportion reaches one-third, and by the end of the third month it exceeds one-half. In both sexes the first week of life is by far the most destructive to infant life. Thus we note that one out of every 35 males born, and one out of every 46 females born, perishes within a week of birth. In the first week of life the mortality of male infants is higher by nearly one-third than that of female infants. The excess in the male rate remains nearly constant for several months and then decreases irregularly until, in the fourth and fifth years of life, somewhat more female children die than male children.

The high mortality in the first few days after birth is mainly due to the decease of infants who, either from immaturity or from debility at birth, can hardly be regarded as viable. Wasting diseases, including premature birth, congenital defects, atrophy, &c., are the chief causes of deaths occurring at this early age. In the second, third, and fourth weeks of life the mortality falls to less than a quarter of that in the first week. The same diseases still account for a large share of the mortality, but from diseases other than these the mortality in successive weeks of the first month varies but slightly, being somewhat higher in the second than in the first half of that period.

¹ A previous notice of this report appeared in THE LANCET of Feb. 16th, p. 450.

annual death-rate of 1·6 in Smethwick, 3·7 in Grimsby, and 5·1 in St. Helens. The 95 deaths from whooping-cough showed a marked decline in the numbers in recent weeks; the highest rates therefrom were 1·2 in Rochdale, 1·7 in Rotherham, and 2·6 in Middlesbrough. The 65 deaths referred to diphtheria also showed a decline, the disease being proportionally most fatal in Derby and in Wigan. Scarlet fever caused eight deaths in London, five in Birmingham, and three each in West Ham, Sheffield, and Hull. The deaths referred to "fever" were exceptionally few. The fatal case of small-pox occurred in Bristol. No case of small-pox has been under treatment in the Metropolitan Asylums Hospitals since the end of June last. The number of scarlet fever patients under treatment in the Metropolitan Asylums Hospitals and in the London Fever Hospital, which had steadily declined in the eight preceding weeks from 3846 to 3035, further fell to 2928 in the week under notice; 322 new cases of this disease were admitted to these hospitals during the week, against 311 and 368 in the two previous weeks. The deaths in London referred to pneumonia and other diseases of the respiratory organs, which had been 528 and 527 in the two preceding weeks, declined to 379 in the week under notice, and were 59 below the corrected average in the corresponding week of the last five years. The causes of 58, or 1·1 per cent., of the deaths registered during the week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in London, Leeds, Bristol, West Ham, Salford, and in 48 other of the 76 towns; the proportion of uncertified deaths, however, again showed a marked excess in Birmingham, Liverpool, Gateshead, South Shields, and Tynemouth.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in eight of the principal Scotch towns, which had been equal to 23·0 and 22·0 per 1000 in the two preceding weeks, further declined to 18·8 in the week ending Feb. 23rd, but exceeded the mean rate in the 76 English towns by 1·0. The rates in the eight Scotch towns ranged from 14·6 and 15·9 in Aberdeen and Paisley, to 20·3 in Glasgow and 20·8 in Dundee. The 654 deaths in the eight towns showed a further decline of 110 from the numbers in the two previous weeks, and included 71 which were referred to the principal epidemic diseases, against 105 and 84 in the two preceding weeks. These 71 deaths were equal to an annual rate of 2·0 per 1000, which exceeded the rate from the same diseases in the 76 English towns by 0·7; they included 27 which were referred to whooping-cough, 25 to "fever," 10 to diarrhoea, six to diphtheria, two to measles, one to scarlet fever, and not one to small-pox. The 27 fatal cases of whooping-cough exceeded the number in the previous week by seven, and included 20 in Glasgow, three in Greenock, and two each in Edinburgh and Aberdeen. The 25 deaths referred to "fever" were fewer by 24 than the number in the previous week, including 21 in Glasgow, and two both in Edinburgh and in Paisley; 19 of the 21 in Glasgow and all the four in Edinburgh and Paisley were certified as cerebro-spinal meningitis. Of the six fatal cases of diphtheria, two occurred in Paisley. The deaths in the eight towns referred to diseases of the respiratory organs, including pneumonia, which had been 178 and 163 in the two previous weeks, further declined to 161 in the week under notice, but exceeded the number in the corresponding week of last year by 39. The causes of 23, or 3·5 per cent., of the deaths registered in the eight towns during the week were not certified or not stated; the mean proportion of uncertified deaths in the 76 English towns during the same week did not exceed 1·1 per cent.

HEALTH OF DUBLIN.

The annual death-rate in Dublin, which had been equal to 21·8, 28·6, and 31·4 per 1000 in the three preceding weeks, declined to 27·1 in the week ending Feb. 23rd. During the first eight weeks of the current quarter the death-rate in the city averaged 28·6 per 1000, the mean rate during the same period not exceeding 20·1 in London and 21·6 in Edinburgh. The 203 deaths of Dublin residents during the week under notice showed a decline

of 32 from the high number in the previous week, and included nine which were referred to the principal epidemic diseases, corresponding with the number in the previous week. These nine deaths were equal to an annual rate of 1·2 per 1000, and included three from whooping-cough, three from diarrhoea, two from "fever," one from diphtheria, and not one either from small-pox, measles, or scarlet fever. The fatal cases of whooping-cough showed a further decline from recent weekly numbers. The deaths in the city included 37 of infants under one year of age and 51 of persons aged upwards of 65 years; the deaths of elderly persons were fewer than in any previous week of this year. Nine inquest cases and seven deaths from violence were registered during the week; and 71, or 35·0 per cent., of the deaths occurred in public institutions. The causes of five, or 2·5 per cent., of the deaths registered during the week were not certified; the percentage of uncertified deaths in the week under notice was 5·9 in Edinburgh, whereas every death in London was duly certified. The 146 deaths in Belfast during the week ending Feb. 23rd included 12 which were referred to cerebro-spinal fever or to cerebro-spinal meningitis.

THE SERVICES.

THE NEW SCHEME OF ARMY REORGANISATION.

Mr. Haldane on Monday last in a long and elaborate speech put the House of Commons in possession of his scheme of army reorganisation. He referred to the deficit of men in the Army Medical Department as "very serious indeed." His remarks on the subject will be found in our Parliamentary columns. With regard to the scheme generally it may probably be said to be on the whole and under existing conditions about the best which has yet been devised. But it is too comprehensive in character to be appreciated in its entirety and it is impossible to foretell how it will work out in practice. It is not easy to create an "army on the cheap," especially a good one. It remains also to be seen how far reliance can be placed on the patriotic sentiment and national sense of duty on the part of the youth and young manhood of this country to make it a success. While there is no room for doubt about Mr. Haldane's honesty of purpose and belief there will still remain much room for misgiving among all those who have not already made up their minds on the subject.

ROYAL ARMY MEDICAL CORPS.

Colonel Ernest H. Fenn, C.I.E., is placed on retired pay (dated Feb. 16th, 1907). Lieutenant Godfrey F. Rugg, from the Seconded List, to be Lieutenant (dated Feb. 10th, 1907).

Lieutenant-Colonel E. Eckersley has been appointed a recruiting medical officer in London. Captain J. C. Kennedy, from the Eastern Command, has joined the London District for duty. Captain J. M. Cuthbert has taken over temporary charge of the Glencorse Military Hospital.

ROYAL ARMY MEDICAL CORPS IN INDIA.

The following officers embarked from England on Jan. 23rd: Lieutenant-Colonel M. W. O'Keefe, Major J. Hennessy, Captain R. Rutherford, Captain J. S. Gallie, and Lieutenant M. J. Cromie. Lieutenant-Colonel W. T. Swan has been granted extension of sick leave from Jan. 20th, 1907, to date of embarkation for India. Major Boyle has been ordered to Agra from Bareilly Brigade and Major L. Way ordered to Allahabad from Calcutta for duty. Lieutenant Keane has been ordered to Meerut for duty in the Station Hospital on completion of course of instructions in sanitation at Lucknow. Lieutenant A. A. McNeight has been transferred to Allahabad for temporary duty. Lieutenant W. C. Nimo has been transferred to Fyzabad on completion of course of instructions in sanitation at Lucknow. Lieutenant-Colonel R. E. Molesworth's passage on the *Plassy*, sailing March 6th, has been cancelled.

ARMY MEDICAL RESERVE.

The undermentioned to be Lieutenants on probation (dated Feb. 1st, 1907): Archibald Crawford Adams, Cecil Ewing, and William Mitchell Browne. Alfred Sutton Millard to be Lieutenant (dated Feb. 1st, 1907).

IMPERIAL YEOMANRY.

Duke of Lancaster's Own: Frederick James Green to be Surgeon-Lieutenant (dated Jan. 18th, 1907). Mont-

to recover compensation on account of it, and it is satisfactory to see that juries can, and may, appreciate this. They are not, as a rule, subject to any tendency to be unduly lenient to defendants in actions for libel, as all newspaper proprietors know.

Medical and Legal Presumption of Survivorship.

The recent terrible loss of life on board the wrecked steamship *Berlin* brings into prominence a question of considerable interest from a medical as well as a legal point of view—namely, the question of survivorship. The presumption as to survivorship may become important with regard to the devolution of property; common instances affording occasions for questions of survivorship arising occur when two persons (especially when two relatives) perish in the same calamity, such as a wreck, a battle, or a conflagration. Direct proof can seldom be procured in these cases. In the Roman law and in several other codes recourse is had to artificial presumptions whenever the particular circumstances connected with the deaths are wholly unknown, such presumptions being based on the probabilities of survivorship resulting from strength, age, and sex. Thus, if a father and son perish together in the same shipwreck or battle Roman law presumed the son died first, if he was under the age of puberty; but if he was above that age that he was the survivor, the principle being that in the former case the elder is generally the more robust and in the latter the younger. The French Code has regard to the ages, and presumes that of those under 15 the eldest survived and that of those above 60 the youngest survived; that if one of the parties were under the age of 15 and the other above the age of 60 the former survived, and that if both parties were between those ages, but of different sexes, the male survived unless he were more than a year younger than the female, but that if they were of the same sex the survivorship of the younger must be presumed. The same rules were in force in the Territory of Orleans at the time of its cession to the United States and have since been incorporated into the Code of Louisiana. They have also, with some modifications, been adopted into the State of New York. But in the law of England there is no presumption of law arising from age or sex as to survivorship among persons whose death is occasioned by one and the same cause. Nor is there any presumption of law that all died at the same time. The question is one of fact, depending wholly on evidence, and if the evidence does not establish the survivorship of anyone the law will treat it as a matter incapable of being determined. The *onus probandi* is on the person asserting the affirmative. In *Wing v. Angrave* (8 H. L. C. 183) two persons, husband and wife, made their separate wills. In the husband's will the property was given to his wife, "and in case my wife shall die in my lifetime" then to W. W. in trust for the children on their coming of age, and in case all of them should die under age then to W. W. for his absolute use and benefit. In the wife's will (made under a power given by her deceased father, in default of the exercise of which the property was to go to relatives specifically named) the property was given to the husband (subject to interests in the children), "and in case my husband should die in my lifetime" then to W. W. absolutely. The husband and wife and two children perished at sea, being all swept off the deck by one wave and all disappearing together. It was held by the House of Lords that there was no presumption that the husband had survived the wife or the wife the husband. The principles thus established must be considered as the actual law governing the courts of England and their reasonableness will hardly be disputed. They discard theories which are at best founded on mere conjectures which can rarely, if ever, be verified. The principles on which the courts of England act appear to be recognised and acted on to a certain extent by Holland and the German and Scandinavian States, while in the south of Europe, Italy, France, and Spain the doctrines of the Roman law prevail.

Barberio's Reaction for Semen.

In the *Semaine Médicale*, 1906, p. 476, M. Levinsohn describes Barberio's reaction for the identification of semen and draws attention to its superiority over other methods. A concentrated aqueous solution of picric acid is added to one drop of the suspected semen or its concentrated aqueous solution. In the presence of semen rhomboidal crystals, yellow in colour, are formed. This is a delicate microscopical reaction; it is alleged to have the advantage that it is only

produced with the semen of man, thus excluding the semen of various animals and the other secretions and excretions of the human body. The reaction occurs even in the absence of spermatozoa from the semen, a point of importance in cases of blennorrhagic bilateral epididymitis, when the ordinary microscopical method is useless.

Looking Back.

FROM

THE LANCET, SATURDAY, Feb. 28th, 1829.

POPULAR FEELING FROM THE LATE TRIAL.

A MAN went to Bartholomew's a few days ago, complaining of hydrocele, and was placed under the care of Mr. EARLE. He was told he would soon be cured; and on Saturday last, was desired to go into the operating theatre, where it was intended to tap him. When he arrived, the theatre was crowded to excess, and the first object that attracted his attention was Mr. Earle standing by the table, with a trocar in his hand ready to operate. "Oh!" said the patient, "is this it? No, my lads; I have heard of that Barnaby Cooper's operation for the stone, in the Borough, and you don't take any stone from me, depend on't; besides, my friends don't know where I am." And having thus expressed his determination, he bolted, amidst the loud laughter of the pupils. A chimney-sweeper was waiting just by, to have a cancer of the scrotum removed; but on seeing the other man make so hasty an exit, he took to his heels in the same manner, and was no more seen or heard of.

THE COMMON BUCK-BEAN, OR MARSH TREFOIL, AS A SUBSTITUTE FOR HOPS.

Mr. Yosy communicated to the Medico-Botanical Society, that the above-named plant is used in Germany as a substitute for hops, and contains the bitter principle in greater abundance than the common hop. The leaves should be gathered in the spring, and dried in the shade. It is also employed in brewing porter in Sweden, and it is said to have been introduced there by an English sailor, in 1789. For this communication, the Society presented to Mr. Yosy their silver medal.—*Transactions of the Medico-Botanical Society*, No. 1.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN 76 of the largest English towns 8250 births and 5469 deaths were registered during the week ending Feb. 23rd. The annual rate of mortality, which had been equal to 20.9 and 20.4 per 1000 in the two preceding weeks, further declined to 17.8 in the week under notice. During the first eight weeks of the current quarter the death-rate in these towns averaged 19.8 per 1000, the rate during the same period in London being 20.1. The lowest annual death-rates in the 76 towns during the week were 6.9 in King's Norton, 10.7 in Leyton, 11.6 in Derby, and 11.8 in Smethwick; the rates in the other towns ranged upwards to 24.8 in Stockport, 25.5 in Brighton, 27.7 in Middlesbrough, and 27.9 in Hanley. The 5469 deaths in the 76 towns showed a further decline of 780 from the high numbers in recent weeks, and included 390 which were referred to the principal epidemic diseases, against 466 and 412 in the two preceding weeks; of these, 136 resulted from measles, 95 from whooping-cough, 65 from diphtheria, 39 from diarrhoea, 38 from scarlet fever, 16 from "fever" (principally enteric), and one from small-pox. The deaths from these epidemic diseases were equal to an annual rate of 1.3 per 1000 in the 76 towns, to the rate from the same diseases in London being only 1.2. No death from any of these epidemic diseases was registered last week in York, Sunderland, Walsall, Hanley, or in 12 other of the 76 towns; the annual death-rate therefrom, however, ranged upwards to 3.3 in Rotherham, 4.4 in Grimsby, 4.6 in Middlesbrough, and 5.6 in St. Helens. The 136 fatal cases of measles showed an increase upon recent weekly numbers; they caused an

work. Malarial cachexia and the enfeeblement resulting from Indian service greatly handicap these discharged men in seeking employment in the labour market against healthy men. It is true more work is done by the officer and the soldier, but the eight-hour day's work of civil life is still hardly dreamed of in the barracks, and so parents resent their boys entering a calling very poorly paid, and which weakens by its routine that development of character that a full day's work produces and on which the future of the nation depends. When people, ignoring all these drawbacks, play the card of "compulsion" I tramp it with that of "betterment"—better training, better payment for officers and men, a higher ideal of service and duty to England, and on her part more sympathy with those on whom the "burden of Empire," that most exhausting and enervating strain, weighs with killing force.

In my opinion, at any rate, the army should be a high school for the young men of the land and a training institution raising each individual in it to higher ideals. Education should be fully carried out and the well-chosen officers, well paid and well treated, should live most devotedly for England and she will amply repay them if they care for her sons serving in the army. I say with much pleasure that one corps of officers have never in the past failed in this splendid betterment service. The work done in past years by the medical officers for the "betterment" of the soldier's life has been too devoted for words. Greatly handicapped and weakened by defective status in the past ages of ignorance and neglect they struggled hard and often broke down in the fight for justice for the soldier.

Had their rational, scientific, and common-sense views prevailed in the dark ages of the past army history the defective prestige of the soldier's life that now is dying out so slowly in England would never have existed, and like the police or the post office or any other public national employment a stream of the finest of our young men would with short service be pouring into the service to benefit by its teaching, as the young Dane to-day benefits by the "popular high schools" of that progressive land.

Any medical man who desires to see the soldiers at the "punishment drill" that physically weighs down the young soldier's heart and shakes his circulation has only to halt his carriage any day in front of the railings of Wellington Barracks in London and join in the crowd that day by day looks on to see the soldier at that old-world "pillory-like" punishment of "defaulting punishment drill," driven about the square by ignorant provost sergeants, and hustled "to make a Roman holiday" in front of a crowd of onlookers. Not all the tinsel glamour and allurements of the recruiting sergeants in Trafalgar Square can wipe out the injurious effects of this wretchedly old-world and public punishment daily going on before the public eye within a stone's throw of the Park. Yet a 6d. fine would quite suffice and easily wipe out the offences so punished.

All this, and much more, has to be removed and abolished within the army, and when it is done and betterment comes we shall need no "compulsion." I trust medical men in civil life will inquire into all these matters before becoming *conscriptivists*. To them I can appeal with confidence because they know the sanitary needs of the military as of the civil population and hard at work themselves can measure by their trying days of duty the easy-going life that still in certain corps, to the detriment of the nation, survives within the army. I close my letter with these watchwords, "BETTERMENT AND NO CONSCRIPTION," and appeal to all medical men to stand by this programme.

I am, Sirs, yours faithfully,

GEORGE EVATT,
Surgeon-General late A.M.S.

Junior United Service Club, London.

THE CURRANT AS A FOOD.

To the Editors of THE LANCET.

SIRS,—The "true inwardness" of the effort which has for some time been made to "boom" the currant as not only an eminently digestible but also as a highly nutritious article of diet would be both amusing and instructive if this were the proper place for expiring it. Mr. J. Cantlie has not at all exaggerated the objections to the currant from the point of view of digestibility. The currant is, of course, only a small grape, but with a proportionately tougher and less digestible skin than the ordinary grape and with relatively more of it on the well-known principle that the smaller a

globular body is the larger in proportion is the ratio of its surface to its contents.

If we are to recommend any dried form of grape for dietetic use surely it would be more rational to advocate the use of sultana raisins than currants. It is rather an ambiguous recommendation of the currant to say, as Mr. Haydn Brown does, that in bread it will "cause the least harm." As to the preposterous advertisements about the highly nutritive value of currants, until those who are responsible for them can show that the juice of the currant, like that of the grape, contains anything more than a little sugar and a trace of albuminoid and saline matter, it is a mere waste of time to discuss the subject.

I am, Sirs, yours faithfully,

Gloucester, Feb. 23rd, 1907. FRANCIS T. BOND, M.D. Lond.

ON THE CONDITION OF THE BLOOD-VESSELS DURING SHOCK.

To the Editors of THE LANCET.

SIRS,—May I be permitted to make a correction in your report in THE LANCET of Feb. 23rd, p. 507, of my remarks in discussing Mr. J. D. Malcolm's paper at a meeting of the Royal Medical and Chirurgical Society on Feb. 12th. The report says that I "did not believe that the treatment of shock by the application of heat was attended by any beneficial result." To have given anyone the impression that such was my opinion I must have been more than usually halting and inconsequent. I am, in truth, quite innocent of heterodox views on the subject of shock and I accepted with all humility the statement that the application of warmth exercises a beneficial influence in the treatment of that condition. Mr. Malcolm had instanced this beneficial influence in favour of his view that the blood-vessels are contracted in shock. What I endeavoured to say in the course of my criticism of his arguments was that the beneficial influence of warmth was due in all probability partly to its agreeable effect upon the patient and largely to the fact that it tended to prevent undue loss of heat from the surface of the body; and that, further, the action of warmth upon the calibre of the blood-vessels being that of dilatation and the blood-vessels being unduly dilated in shock, such action, if it existed, which I did not believe, would be harmful and not helpful.

That the blood-vessels in shock are dilated and not contracted seemed to me to be abundantly clear from the writings of Crile, Leonard Hill, E. H. Starling, Lockhart Mummery, and others, to whose very convincing arguments Mr. Malcolm's paper had, in my judgment, opposed nothing of any real importance. There are other points on which, judging from the report, my incoherence would seem to have misrepresented me, but inasmuch as they portray me merely as an orthodox platitudinarian bore, and not as a propagandist of dangerous therapeutic heresies, I forbear to trouble you on the subject.

I am, Sirs, yours faithfully,

York-street, W., Feb. 23rd, 1907.

LEONARD WILLIAMS.

BURIAL BY THE STATE.

To the Editors of THE LANCET.

SIRS,—In THE LANCET of Feb. 16th, p. 463, under the above heading, is a letter from Mr. S. P. Wills which, while expressing "wonder that the matter of burial by the State has not been made a subject of practical legislation" and indicating the details over which control is considered desirable, touches also on the collateral points of premature burial and the "earth-to-earth" and cremation systems of disposal of the dead. That these topics are highly important, intimately bearing on the individual and the community, cannot be questioned; they have already been freely handled in the press, yet no sufficient legislative action has been taken except in the case of cremation, for which necessary safeguards prior to permission to act have been promulgated. The matters touched upon range themselves under two headings: (1) action desirable on death supervision; and (2) disposal of the body subsequently; and while the efficient control of the former is beyond all doubt the duty of the State, that of the latter, more especially as bearing on one sole mode of burial and its associated details, is open to question. May I say a few words on these points?

At the present time we have a condition of affairs which,

of weights and measures commonly known as the metric system" may seem drastic, but the arguments in its support seem to me incontrovertible.

I am, Sirs, yours faithfully,
Feb. 25th, 1907. D. D. D.

ITALIAN MUNICIPAL ABATTOIRS.

A VISIT TO THE MILAN AND VEROCELLI SLAUGHTER-HOUSES.

(FROM OUR SPECIAL SANITARY COMMISSIONER.)

If the laws of Italy relating to public health questions are examined it will seem that Italy must be quite an ideal nation. The fact is that United Italy has only been in existence for a very short time and as the laws were but recently enacted they were naturally based on the best models. But between the law and its application there is a wide space. Still, it is something to know that in Italy the counsels of perfection do not conflict with the law. Thus, in an old country like England the law says that the authorities may, if they choose, build a public slaughter-house. Of course, the result is that only a very small number of local authorities have availed themselves of this permission. But the Italian *Regolamento* of August 15th, 1890, emphatically states that all communes with more than 6000 inhabitants must construct public abattoirs. Further, only a technically qualified person—that is to say, a veterinary surgeon—must be appointed as director or manager of these abattoirs. Then the law gives minute details in regard to their construction, so that they shall be thoroughly sanitary buildings. There must also be a place where animals can be kept for a period under observation and there should be a steriliser and a destructor. The last two stipulations have been carried out on a very large scale in Italy. But in other respects there is a terrible difference between the law and the reality.

M. Pion, a well-known authority on these subjects, writing in the *Semaine Vétérinaire* of 1893, says:—

When some 30 years ago a number of slaughter-houses were built they were not supplied with sufficient water nor was enough room allowed. The means provided for suspending the carcasses were not numerous enough and they were complicated, cumbersome, and difficult to manoeuvre. In most cases they are similar to the very mediocre abattoirs of the South of France, where, under so powerful a sun, there should prevail absolute cleanliness. The slaughter compartments or sheds are paved with flag-stones and there are gratings and openings where the blood flows down and mixes with excremental matter, finding its way by a sewer to a river which is generally near at hand. Sometimes the abattoir is near the seaside, as, for instance, at Bastia and Donisefio. The fish, the seagulls, birds of prey, and dogs then play the part of scavengers. At the same time foul odours testify to the absence of sanitation. Much the same may be said in regard to most slaughter-houses on the borders of the Mediterranean, however important they may be. But there is one corrective. During the summer very few animals are slaughtered and no hogs whatsoever.

From this it will be seen that the state of affairs in Italy is not described as perfect and that the law remains to a large extent a dead letter. Nevertheless, the public abattoirs at Rome, which were completed in 1892, possess many modern improvements. There are a quarantine section, a destructor, a post-mortem chamber, and baths for the attendants; there are no private compartments for slaughtering but large halls where concealment is impossible. The principal fault is that the space, 50,858 square metres, is not sufficient for a population of about half a million. The cost was £280,000, or 14s. 6d. per inhabitant. Many other towns propose to follow the example of Rome and to build something more like modern and sanitary slaughter-houses. This is notably the case at Genoa and at Milan.

The slaughter-house of the latter town I was able to visit. In a general sense it recalls the abattoir of La Villette at Paris. There are the long rows of private compartments giving on to a roofed court, but it is not a glass roof. In Paris complaints are made of the excessive heat when the sun shines on the glass. At Milan this grievance would be more insupportable. But, on the other hand, the roof is here held up by a series of pillars rising a considerable height above the buildings on each side of the court. Thus there are a free passage of air and some light. Only a very narrow ray of sunshine reaches the floor of the court, and of course in a climate like that of Italy the object is to obtain as much air but also as much shade as possible. Apart from this the disposition is very similar to that of the Paris abattoir (see illustration in THE LANCET of Jan. 12th, p. 125). On both sides is the

long succession of double doors as if it were a row of coach-houses. Each butcher hires one of these compartments, but throws these doors wide open when he is slaughtering and does some of the work outside. The bullocks and other animals are driven into these compartments where they may see at the farther end carcasses hanging from cross-beams. Much filth falls on the floor as the intestines are cleaned out on a marble slab placed in a corner of each of these compartments. The darkest corner seems to have been selected for this purpose—namely, between the door and the side wall, just where the light entering by the door cannot reach. Near the slab there is an opening to a drain in the angle of the wall. Here the small intestines are cleaned out and their contents fall on the floor. This recalled the filthy spectacle to be seen at La Villette during slaughtering time and is far from satisfactory. These small compartments only contain very rudimentary contrivances. Above there are two huge wooden rafters crossing the compartment at a height of from 12 to 14 feet. A triangular wooden apparatus, something like an artist's easel, is used to raise the carcasses. This tripod is armed with a pulley and crank. Thus the carcass of a heavy animal may be lifted and suspended to the cross-beams, but it could not be moved backwards or forwards or the halves separated. The intestines fall on the floor; the stomach is thrown into a wooden tank which is lifted by hand and emptied in the open shanty where the manure awaits removal.

The place for the slaughtering of hogs is bad but still there are plenty of light and air and a good, sound, water-tight cemented floor. The walls are not enamelled or made of washable material, so that the blood and dirt adheres to, and sinks into, them. But there are good sound troughs for washing out the intestines that can easily be kept clean. The sheep slaughter-house is much in the same condition. The surrounding walls are armed with long spikes and on these are hung the carcasses of the sheep, where they remain in the unsuitable atmosphere and dirt of the shambles. Then there is quite a large horse slaughtering department which is the worst constructed part of the abattoir. Here for air and light there are but the door and windows on one side, and only very few openings in the roof. Though a good deal of horseflesh is eaten the horse-tripe is thrown away. The place where the tripe from bullocks, &c., is washed and prepared is large, lofty, but dirty. Above there are many rafters with cobwebs hanging down in great numbers. For washing and soaking very large broad wooden tubs are used. These are fine specimens of cooperage and look picturesque, but stone or metal, not wood, is the material that should be employed.

The stables are more insanitary than the slaughtering department. Light is admitted on one side only and the structures are low and very imperfect. Instead of a well-drained water-tight floor the earth is paved with small round stones which let the liquid manure pass through and facilitate the contamination of the subsoil. Again the offices for the veterinary surgeons and staff looked shabby, dusty, and poor. The German "freibank" system of sterilising tuberculous and other slightly diseased meat, which was so well explained by Dr. Hugh A. Macewen when dealing with German methods of meat inspection in a recent number of THE LANCET,¹ is applied here. This flesh after it has been exposed to heat in a steriliser for a sufficient time is sold to the poor at the rate of 60 centimes the kilogramme, or about 3½d. per pound. It is the rule at Milan not to sell more than two pounds to each purchaser so that it should not be used in eating or boarding houses. Perhaps what impressed me most favourably was the carts which butchers are made to employ when they carry meat from the abattoir to their shops. These are light vehicles and in no wise ungainly. They close completely, but near the top there are on each side narrow apertures to let the air pass but not large enough to admit flies or any great quantity of dust. They are of different sizes, some small enough to be pushed or pulled along by one or two men, but so far as the meat is concerned the form of inclosure or protection is the same. The meat is also well shielded from the heat. This is a detail which needs emphasising in England and particularly in London. Here no special care is taken as to the handling and conveying of carcasses and meat; there is no such thing as a regulation butcher's cart such as may be seen any day in the streets of Milan.

As a contrast with Milan, which is one of the largest

¹ THE LANCET, Feb. 2nd, 1907, p. 312.

as shown by the Parliamentary inquiry of 1893, provides "no safeguard against criminal attempts on life," forms "no trustworthy record of disease," and requires no reasonable proof of death, so furnishing an occasion for premature burial with possible accompanying horrors; yet surely it would be no difficult task to frame a few regulations which would necessitate full professional inspection by recognised and authorised officials in every case of notified death, which would require removal of the body to a public mortuary where the conditions made such action necessary on sanitary grounds, for its retention for a reasonable period pending disposal, and which would prevent burial or other disposal of the body without the certificate of the authorised official, drawn up shortly before the closure of the coffin, as to the fact of death and its causation? That the chances of concealment of foul play and of premature burial would be reduced to a minimum, that sanitary requirements would be met, and the causations of death be placed on a more reliable and scientific basis than at present pertains will not be questioned; yet we permit the present haphazard and dangerous practice to continue. Here surely the need of State intervention on death notification, for the well-being of all, is placed on an undisputable basis as a matter of duty; the facts are clear and well known to the thinking community and to the legislature; action only is wanted. And at the present time we have two methods in operation for disposal of the body—vault or earth consignment in a coffin and cremation. By the former process as usually carried out we now, just as older races did and probably now as then under the influence of religious views bearing on the resurrection of the body, oppose the natural resolution of our mortal frames through the wholesome and beneficent earth's action by inclosure in metal or strong wooden surroundings; yet we do but delay the process of disintegration thereby and give occasion to its passing through a phase of decomposition, unaccompanied by the disinfecting power of porous soil, which because it is out of sight is out of the mind of the majority of individuals though no less horrible in fact. That "earth-to-earth" burial in properly selected ground would meet the requirements of sanitation and follow closely nature's plan may be granted and there seems no reason why such a satisfactory committal to the grave cannot be effected under our existing custom with no more offence to the living than is produced by contact of the earth with the dead, some slight covering intervening. The necessary departure from our present proceedings would be some mechanical arrangement by which the top and sides of the coffin could be removed after placement in the grave and before returning the excavated soil. It may be replied that the collapsible coffin practically effects all that is needed. But is this so certain? One outcome of strict "earth-to-earth" burial would, I think, follow, and this is no small matter to those who dread the possibility of premature burial: no return to consciousness would ensue should life not be extinct. In regard to vault burial it is difficult to adduce a single point in support of it; and though in our islands committal of the body to the sea might be advocated in the future, when accumulating burials as now effected have curtailed the available desirable ground, the only other mode open to those who have a repugnance to coffin burial, for various reasons, is cremation. Mr. Wills regards it with horror; others, however, are clearly not of his way of viewing the process. Its sanitary advantages are apparent: it is rapid and effective in action; by it resolution of the body into its elements differs not from that of earth burials except in the chemical combinations effected; through preliminary necessary legal requirements the possibility of concealing malpractice is reasonably excluded and the fears of premature burial do not come into existence; it is stated not to be more costly than grave burial. Though stigmatised as "heathenish" by some, its position is essentially the same as earth burial; both systems preceded Christianity and both are now practised under it; the real principles involved in both are not those of religion but of sanitation and social jurisprudence.

Whether the time is not a ripe one for pressing home the necessity of proper regulations preceding the disposal of the dead, now that we have a political party in power whose supposed essence is social reform, is a question well worth consideration, but in respect to the permissible modes of disposal of the dead, subject to such sanitary and other safeguards as may be necessary for the well-being of the community as a whole, is not the matter rather one for the

individual to decide for himself? And is it not for the individual with fears of premature burial to take such counter-acting precautions as may suggest themselves pending the provision of proper legislative enactments by the State?

I am, Sirs, yours faithfully,

FRANCIS H. WELCH, F.R.C.S. Eng.

Lee, S.E., Feb. 16th, 1907.

THE CENTRAL MIDWIVES BOARD.

To the Editors of THE LANCET.

SIRS.—I notice in THE LANCET of Feb. 16th a report of the meeting of the Central Midwives Board and in the last paragraph it is stated that "the charge alleged against a midwife—A. L. Bellis—by the local supervising authority of Southampton was considered and the Board decided that she should be severely censured on her own admission of having made a false declaration of stillbirth."

I may say that the local supervising authority has not made any such charge against Nurse Bellis, nor has the local supervising authority communicated with the Central Midwives Board respecting her; furthermore, the local supervising authority has no official knowledge that she has been censured by the Central Midwives Board. I received the notice of stillbirth from her, and at the coroner's inquest she explained that it was a breech presentation, and that the child was partly born on her arrival. It would appear to me that she had a perfect right to give a certificate of stillbirth, but through a misapprehension she put "B.B.A." on the certificate. I placed so little importance on the nurse's mistake that I did not report the particulars to the local supervising authority.

Trusting you will give these remarks the same publicity as your report of the meeting of the Central Midwives Board of Jan. 31st,

I am, Sirs, yours faithfully,

R. E. LAUDER, M.D. Durh.,

Medical Officer to the Local Supervising

Southampton, Feb. 27th, 1907.

Authority.

THE ADVANTAGES OF THE METRIC SYSTEM.

To the Editors of THE LANCET.

SIRS.—The Decimal Association is doing good work in helping to bring about the consummation so devoutly to be wished—namely, the adoption of a decimal system of weights and measures and coinage in the United Kingdom. Everyone, I suppose, is convinced of the absurdity of the present system, if such it can be called, for there is absolutely no uniformity in it, consisting, as it does, of a bewildering number of weights and measures of various origins. There must be real reform and there can be no adjustment or adaptation of such a clumsy system; it must go altogether in favour of metric measures applied to all the branches of standardisation, weight, capacity, length, and even coinage. The trouble is to appoint the exact moment when the old system is to be made obsolete and the new system current, but the experience of other civilised countries has proved that the difficulty of change is not as great in practice as might be thought. Further, there is no non-metric country left to worry us as we have worried others. The following is an interesting calculation, and there are scores of others in regard to the immense saving of time which would be effected if the metric system was adopted. Schoolmasters have estimated that the saving in educational time by the exclusive adoption of the metric measures would be about 200 hours per year per child. If coinage were decimalised the saving would be increased to about 350 hours—that is, about 200,000,000 hours a year for ever of school children's time can be saved by a reform which would cost adults on the average about the equivalent of a day's work. This seems alone worth while bringing about the reform in earnest apart altogether from the gain to commercial and scientific workers. We should then worry no longer about the equivalent of metres in inches (of which three barleycorns make one), of grams in grammes, of kilogrammes in tons, of pints in litres, of shillings in francs, and so on *ad nauseam*. Most of us, especially those who are compelled to make scientific calculations, hope that the Weights and Measures (Metric System) Bill ordered recently by the House of Commons to be printed will receive full, careful, and unbiased consideration. A Bill "to render compulsory the use of the system

know what must be done with the infirmary site now that they have got it. The scheme most frequently talked of has been to build a free library and an art gallery under one roof. Another idea strongly advocated by some, and worthy of consideration, is to preserve it as an open space. The curious objection raised to this is that the space will be or look so large that the shops and warehouses in the surrounding streets will be dwarfed, a matter which would not be a grief to those rejoicing in the open space. Another project seriously put forward by one of the city council is to have not only a free library and art gallery but also colonnades and various fine things, with 250 shops. These are, I believe, more in number than those in the chief shopping streets, and if they were to succeed it would be at the expense and ruin of a good many of the shopkeepers. If they did not succeed the corporation would not get its rent, and the loss from the experiment would fall on the ratepayers. The scheme of a committee of the corporation, together with other schemes, had a long discussion given to them at the last meeting of the council. In the end the matter was referred to the committee to see if it could not devise some plan of getting revenue, in addition to providing a temple of literature and art.

Feb. 28th.

LIVERPOOL.

(FROM OUR OWN CORRESPONDENT.)

The Health Committee; Cerebro-spinal Meningitis; Insanitary Houses.

At a meeting of the health committee held on Feb. 21st allusion was made to the fatal case of "spotted fever" which had occurred in the city. Dr. E. W. Hope (the medical officer of health), in reply to the chairman, said that there was absolutely no need for alarm. Cerebro-spinal meningitis was a disease which rarely appeared, and when it did appear it caused a great deal of attention out of all proportion to its gravity. Week after week and month after month there were deaths from measles and whooping-cough outnumbering this disease by 100 to 1, but the public were so familiar with those diseases that they unfortunately attracted little attention. Dr. Hope said that provision had been made in Liverpool for the isolation of any doubtful cases.—The health committee will on March 6th submit to the city council recommendations to apply the Infectious Disease (Notification) Act, 1889, to cerebro-spinal meningitis for six months as an experiment and permanently to anthrax.—A corporation scheme for the demolition of insanitary houses in the Burlington-street and Brassey-street areas at a cost of £23,250 was the subject of a Local Government Board inquiry in Liverpool last week.

University of Liverpool: Current Topics.

The University of Aberdeen is about to confer the honorary degree of LL.D. upon Professor J. Campbell-Brown, the chief of the department of chemistry at the University of Liverpool. Dr. Campbell-Brown is one of the oldest members of the University staff of professors.—Two more expeditions are to be despatched by the School of Tropical Medicine to West Africa in the course of a few months—one to further investigate the causes of sleeping sickness, and the other to investigate and to report upon blackwater fever.—In view of the Government grant of £1050 to the University, of which £350 is to be apportioned to the expenses of research work, it is interesting to note that there are at present close upon 150 post-graduate students engaged in research work in various departments of the University. The amount of research work at the University is very great and the expenses are considerable, so that this Treasury grant is particularly welcome.

The Royal Southern Hospital: The Tropical Diseases Ward.

The annual meeting of the subscribers to the Royal Southern Hospital took place on Feb. 11th at the town hall under the presidency of the Lord Mayor. An interesting feature of the report was the allusion to the value of the ward set apart for the treatment of patients suffering from tropical diseases. 120 cases were treated in the ward last year. Three cases terminated fatally—viz., one of malarial fever, one of sprue, and one of dysentery with abscess of the liver. The diseases treated were: malarial fever, beri-beri,

dysentery, ankylostomiasis, leprosy, and scurvy. The nationalities included 69 English, 13 Irish, eight Scotch, four Welsh, nine Indians, four Chinese, three negroes from West Africa, two Americans, two French, two Norwegians, one German, one Greek, one Dane, and one from St. Helena. Several ladies from the Colonial Office were trained for special tropical work as nurses. A considerable number of students attended the course of instruction at the School for Tropical Medicine, a large proportion of whom obtained the diploma in tropical medicine after examination at the University of Liverpool. The ward was of the greatest possible benefit to those treated in it and deserved all the support that could be given to it by ship-owners and others interested in the port of Liverpool and especially by those engaged in foreign trade. The income of the general hospital was a little over £9000, whilst the expenditure reached £11,612. The x ray department has been enlarged and a new out-patient department is in contemplation. An appeal is also made for a "Samaritan" fund for the supply of surgical appliances to the indigent poor which is greatly needed. The total number of in-patients treated during the year was 2502. The out-patients numbered 12,075.

Vaccination Statistics for Liverpool and Toxteth Park.

During the year 1905, 5118 and 4091 births were registered in the parish of Liverpool and Toxteth Park district respectively. 4404 (Liverpool) and 3175 (Toxteth Park) children were successfully vaccinated. 10 (Liverpool) and 14 (Toxteth Park) were found insusceptible of vaccination. One conscientious objection was sustained in Liverpool and six in Toxteth Park. 560 (Liverpool) and 427 (Toxteth Park) children died before being vaccinated. None (Liverpool) and 55 (Toxteth Park) vaccinations were postponed by medical certificate. 84 (Liverpool) and six (Toxteth Park) cases were removed to districts the vaccination officers of which had been duly apprised. 59 (Liverpool) and 406 (Toxteth Park) cases were removed to places unknown and two were not accounted for in Toxteth Park. 86 per cent. of the children were vaccinated (on the births) in Liverpool; whilst if deaths before vaccination, removals, &c., are deducted, the percentage of vaccinations in Liverpool reached the extraordinary average of 97. Toxteth Park percentages are not quite so high, but are highly creditable.

Hospital Sunday Fund.

The treasurer of the Hospital Sunday Fund has reported that the amounts remitted to him to date are £8541, being £787 over and above the amount contributed last year.

A Visit to the R.M.S. "Lanfranc": A Miniature Hospital.

The new twin-screw Royal Mail steamer *Lanfranc* of the Booth Steamship Company, which has been built for service between Liverpool and Spanish, Portuguese, and South American ports, lay in mid-stream in the river Mersey on Saturday, Feb. 16th, for inspection, prior to sailing on Feb. 18th on her maiden voyage, and afforded much pleasure and wonder to her numerous visitors. Her principal dimensions are: length, 434 feet; breadth, 52 feet 3 inches; gross tonnage, 6300 tons; her engines will develop about 5000 indicated horse power, and her sea speed is designed to be about 14½ knots. She possesses a promenade deck, a shelter deck, an upper deck, and a main deck. Her sanitary arrangements are all that can be desired. At the after end of the shelter deck is a large lavatory for gentlemen. The ladies' lavatory on the same deck is situated on the port side and contains a novel feature on shipboard in the shape of a sitz bath, to which hot and cold fresh water is supplied. Another feature of interest is the large number of shower baths in both lavatories. The hospital block for first-class passengers deserves particular notice; there are three wards, with special hospital cots in each, two bath-rooms, and a dispensary, all adjoining the medical officer's comfortable apartments. This hospital contains eight cots. The first-class dining saloon is a large and handsome room, with seats for over 200 persons. There are 18 tables, each seating 12 passengers. Fresh air is brought down by two large ventilators at the forward end of the saloon and powerful electric fans insure a good circulation of air under the trying conditions which obtain in the tropics. All the berths are supplied with electric fans. The after end of the ship is fitted up for 350 steerage passengers. The large lavatories and the bulk of the sleeping accommodation are on the upper deck. An effort has been made to combine essential privacy with the free ventilation which a voyage

centres of population in Italy, I visited the slaughter-house of the small town of Vercelli. This latter institution compared very favourably with that of the capital of Lombardy. Instead of a population of 520,000, Vercelli has only 17,900 inhabitants, according to the last census. The abattoir is on the outskirts and fairly well isolated. The special building for slaughtering pigs is quite a modern structure. The floor is water-tight and convex, so that there is a drain on each side. Then there are overhead rails known as the "omnibus" system, so that the carcasses, suspended to little wheels, can be easily pushed in different directions and need not be carried. For cleaning the intestines there are good stone troughs and a large boiler provides a constant supply of hot water. The place for preparing tripe is well apart from other buildings and the floor is carefully cemented and drained. But there is not much tripe prepared here, as a large portion is sold to a dealer who takes it away to some distance from the town. In every part of the Vercelli abattoirs where there is killing the buildings are lofty and open from floor to roof; there is no upper storey. The floor, which is on a level with the earth, is rendered water-tight. Above, under the roof and on both sides of the building, there are permanent openings. These are not windows that can be closed but apertures which cause a through draught which cannot cease day or night. Altogether, considering that Vercelli is but a small town and its financial means must be limited, this slaughter-house was very creditable. At Milan it is recognised that the abattoir is unworthy of the town and I was assured by the mayor and others concerned that a new and model abattoir would be built at no very distant date. Indeed, throughout Italy the desire for really sanitary abattoirs is growing on all sides. This feeling is likely to increase as it becomes more and more evident that, with good management, these institutions can be made to pay financially.

MANCHESTER.

(FROM OUR OWN CORRESPONDENT.)

Poor-law Medical Officers and the Chairman of the Prestwich Guardians.

AT a recent meeting of the Prestwich guardians the chairman made some general and sweeping remarks as to the inattention and neglect of duty on the part of Poor-law medical officers. This naturally excited some notice and at a meeting held on Feb. 21st a letter was read from the medical officers of the union calling attention to the strictures passed by the chairman at the last meeting on the manner in which district medical officers performed their duties and asking that the chairman should state definitely any charge that he might have against them. The result was that the reverend chairman practically withdrew his statements, which were not limited in any way, and would naturally be applied to the medical officers of the Prestwich union before going farther afield. He is reported to have said: "I have to state, in answer to the letter of the doctors, that these strictures do not apply to this union or to any of our present staff or district medical officers. When I illustrated my case for the acceptance of the resolution I proposed, I simply illustrated it by occurrences that have taken place, not necessarily in our union, and therefore I say that the honour of our medical officers has not been impugned and an unfair aspersion has not been cast upon the character of the work done." The strictures thrown broadcast were severe and calculated to injure specially the medical officers of the Prestwich union. Yet there is no word of regret. If the reverend chairman did not intend his strictures to apply to the Prestwich union he should have said so at first. The motion which he had proposed was to the effect that the guardians should be informed of all sick cases. In all probability the medical officers would be well pleased if the guardians visited their sick cases, but of course it should be done solely with the wish to coöperate in benevolent work. However, the medical officers did not lack defenders on the board, and if the disclaimer overtakes the charge no great harm will have been done.

Isolation Hospital at Hollingworth Lake.

An isolation hospital for the joint authorities of Littleborough, Milnrow, and Wardle has been built in the neighbourhood of Hollingworth Lake and was opened on Feb. 16th.

It contains fever wards and an administrative block. The cost of the buildings has been £9130.

Some Hospitals and Infirmarys.

It is a pleasure to hear of a hospital free from debt, even though some philanthropists consider that the weight of a debt hanging on the neck of the committee is an incentive to their energy in the efforts that have to be made to increase old subscriptions and to get new ones. The Royal Lancaster Infirmary was stated to be in this happy state at the annual meeting on Feb. 19th. The income had increased by £104 or more in the year, and was nearly £3500. The expenditure had, as is usual, also increased but only to the amount of £71. At the end of 1905 there was an adverse balance which was wiped out by Lord Ashton, so that for the first time since the new institution had been opened there was a credit balance. There had been a considerable increase in the work of the hospital.—At the annual meeting of the Victoria Hospital, Burnley, it was shown that there was "very urgent need for a substantial extension of the hospital, and that at least £20,000 would be required." The matter is to be brought before a town's meeting, but if a few more of the wealthy residents will follow the lead of the chairman of the governors and give £2000 each, the town's meeting will no doubt approve of the scheme.—The report of the Oldham Infirmary was somewhat depressing. It was stated at the annual meeting on Feb. 18th that the year's working showed a deficit of £869, although the Hospital Saturday collections were the largest on record. The governors wished to say to the people of Oldham and district that if they wanted the infirmary kept up to its present standard they must find at least £1000 a year more than they were now doing. Taking one year with another they required £7250 to keep free from debt. Extensions and furnishing, with incidental expenses, had cost £21,156, and the amount raised was £19,590. The chairman was not dismayed and said "it only needed to be properly put before the people of Oldham, and especially the industrial people, to induce them to recognise that the infirmary had a claim upon them and ought not to be allowed to go into debt." It is to be hoped that this appeal will obtain the desired income.—The Stockport Infirmary likewise shows a deficiency on the year's working; in this case of £373. The income had been £5042 and the expenditure £5415. The accommodation was increased some time ago by 27 beds and the income has never covered the expenditure, the yearly deficit for the last seven years having been £600. To pay the way legacies have been encroached upon. It seems that a small increase of £20 has been made in the subscriptions and there was some increase in the workpeople's contributions which amounted to £1119. The work, of course, increases whatever the income may be. The mayor said that the expenditure worked out at about 1s. 1½ per head of the population and in a wealthy town like Stockport a much larger sum should be raised without difficulty. But philanthropists are prone to forget that there are many other sums of 1s. 1½ or more that must also be raised. Still, in spite of deficits, they look forward in Stockport to the extension of the out-patient department and the provision of a nurses' home.—The story told at the meeting of the Northern—formerly the Clinical—Hospital in Orcheston Hill, road was, like most of the others, a good deal chequered. Last year was the hospital's jubilee and the committee set itself the task of raising £25,000 to pay the debt to the bank, to equip the hospital fully, and to provide a sufficient endowment to put the finances on a more satisfactory basis. At the close of the year £18,092 had been raised but at the meeting the chairman was able to announce that the whole of the £25,000 had been obtained. Still, though in a much better position than it was, the deficiency of revenue, £970, added to previous deficits, amounted to £4000, which would have to be repaid to the bank out of the £25,000; and if the balance were funded, as the treasurer said, it would only bring in about £800 to meet an annual deficiency of nearly £1000. The foregoing accounts may probably be taken as representative of the state of hospital finances all over the country. All more or less in difficulties, some with their heads just above water, while others are nearly submerged. But notwithstanding the work which they are called on to do is ever increasing.

The Infirmary Site.

One of Lytton's novels bears the title "What Will He Do With It," and the people of Manchester do not as yet seem to

certainly prevent in future medical men from entering into a strike.

Settlements for Tuberculous Patients in German South-West Africa.

A committee was formed some time ago for the purpose of settling tuberculous patients in German South-West Africa. As the rising of the natives in this colony has now ceased the committee, which includes medical men as well as other persons interested in colonial matters, has again drawn attention to the advantages of a settlement in South-West Africa. The matter was recently discussed before a meeting of the Berlin Society for Social Medicine. Professor Senator spoke in favour of the plans of the committee, saying that the sanatoriums at home received only patients in the first stage of the disease while it was still curable. A great many tuberculous patients were unable to obtain admission to the sanatoriums either from want of room or from the cases being unsuitable for sanatorium treatment. It was by this class of patients that tuberculosis was spread and benefit would accrue from their removal to a country like South-West Africa, which offered them the best possible chance of recovery. The insurance institutions under the workmen's insurance laws should therefore assist tuberculous workmen desiring to emigrate, as they were authorised by law to do. Dr. Merret said that the climate of the colony was very good for tuberculous patients, but that cardiac diseases were frequent because of the elevation of the country, the capital, Windhoek, being situated about 1800 metres above sea level. No patients in an advanced stage should proceed to the colony, but only those who were still able to work and to earn their livelihood there.

Medical Women in Germany.

Since 1899 women have been admitted in Germany to the State examination in medicine and may therefore become duly qualified practitioners. The universities of the individual States of Germany are, however, by no means uniform in the position which they take up with respect to women medical students. The University of Jena, for instance, does not admit women at all. In all the Prussian universities and in the universities of Strasbourg (Alsace-Lorraine), Rostock (Mecklenburg-Schwerin), and Giessen (Hesse) women are not allowed to matriculate but are admitted only as guests (*Hospitantinnen*) and may attend a lecture or take part in a course only by the special permission of the individual professor or *privat-docent*. Some of the leading professors in the University of Berlin, such as Professor Waldeyer and Professor von Bergmann, decline altogether to admit women. The universities of Leipzig (Saxony), Tübingen (Württemberg), Freiburg and Heidelberg (Baden), and also the three Bavarian universities in Munich, Erlangen, and Würzburg, are the most liberal, as they allow women medical students to matriculate under the same conditions as men. These concessions, however, are available only for German women, whilst for foreigners special provisions exist. As a few years ago women were excluded from nearly all the German universities, the progress made by them is considerable and it is very likely that the restrictions which are still in force at some universities will soon disappear and that women will be treated everywhere on an equal footing with the male students. Notwithstanding the facilities given to women at a good many of the German universities the number of female medical students is relatively small, their total number being, according to information collected by Dr. J. Schwalbe, the editor of the *Deutsche Medizinische Wochenschrift*, only 300, as compared with 7219 male students, equal to 4 per cent. Of these 300 ladies a good many are foreigners, so that a considerable increase of the number of medical women practising in Germany is not very likely to occur. In the beginning of the year 1906 there were only 60 fully qualified medical women registered in Germany.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

Report on Cancer.

THE cancer committee of the Royal Hungarian Medical Society has drawn up a report giving the results of last year's investigations, the chief points of it being as follows. The year's investigations show that cancer is not associated with peculiarities of diet, climate, or mode of life, thereby

confirming the conclusions announced a year ago. The experiments yielded very interesting results, including a demonstration of the possibility of perpetuating malignant new growths through successive generations of mice in such a way that the cancer cells appeared to be gifted with the power of multiplication, for the malignancy of cancer and a clue to the solution of its mystery appear to lie in this abnormal proliferation and reproduction. The property of perpetual multiplication definitely separated cancer from known infective diseases. Much experimental work had been done in treating malignant growths but attempts at immunising with serums did not justify the claims sometimes made for them, although in some cases they deprived the cells of the power of growth. The action of radium and radio-active solutions had been carefully studied. It was undeniable that these sometimes influenced the growth and development of normal and tumour tissues, but there was no evidence yet obtained that radium emanations had any selective or special action on tumour tissues.

Prevalence of Influenza.

Influenza is more prevalent in Hungary this year than it has been for a long time past, and it is a striking feature that influenza bacilli are present in a great many cases of other catarrhal affections. This has been particularly the case during the present winter season. The occurrence of the disease seems to be due either to an increase of virulence or to a lowering of the relative vitality of the patient, for the bacilli may be found even in persons not presenting primary symptoms. Occasionally, perhaps, an association of different bacilli makes inoculation more easy. It is impossible to decide, however, whether there may not be a number of other bacteria grouped as influenza bacilli because of their morphological characteristics, yet without possessing true virulence. It is not impossible that once the disease has begun and passed through several persons the bacilli gain in virulence and so become capable of affecting hitherto immune individuals.

The Pathology of Sciatica.

Dr. Verebely finds that in the literature on the subject of the pathological appearances observed in sciatica there is a general agreement as to the existence of a swelling of the nerves. Some observers, especially in England, have thought that they discovered uric acid in the neurilemma. It seems very probable, however, that these deposits were secondary. In most reported cases the nerve was found to be redder, more voluminous, and less dense than normal. In one case the sheath was found to be loosened, with some dilated veins around the nerve, but there was no sclerosis of the nervous tissue. In another case it was thought that more fat was present in the nerve than normal. Out of the 11 cases reported three were negative pathologically and the eight that were positive showed an increase in size, though without much nerve change.

The Mental Disturbances of Heart Disease.

Dr. Mahler recently read an interesting paper on this subject at a country medical meeting. The paper consisted chiefly of the clinical histories of 13 cases observed by him in which these conditions were associated. He first classified the cases under two groups—(1) mild forms, which did not produce severe mental symptoms; and (2) aggravated forms of organic disease, where the mental infirmities recorded were inferior to the physical. In the severer forms the treatment must be directed chiefly to the physical condition while in the milder forms both may be treated coincidentally. Etiologically he divided the condition into four classes: (1) local conditions, such as palpitation, tachycardia, &c.; (2) pains around and within the heart, such as angina pectoris; (3) secondary lesions of the brain; and (4) disturbances of the circulation.

CANADA.

(FROM OUR OWN CORRESPONDENT.)

Changing the Medical Law in the Province of Quebec.

A BILL of much interest to the medical profession in the province of Quebec has just been introduced into the Quebec Legislature. It is proposed by it to extend the course of medical study from four to five years, to define better what constitutes the illegal practice of medicine, and to define better the powers of the College of Physicians and Surgeons.

the river Lagan, Belmont, Knock, and those portions of the city over 100 feet above sea-level obtain their water exclusively from the Mourne source. Of course, when there is a surplus from the Silent Valley (Newcastle) it is put into consumption in the Woodburn area, the two being mixed in about equal proportions. The two houses from which were taken the samples commented on by Professor Symmers in his report are both in the area supplied from the Woodburn and the Mourne districts.

Cerebro spinal Fever in Belfast.

There can be no question that the epidemic of cerebro-spinal fever so prevalent in Belfast presents many difficult problems for solution. 1. Is it in any ordinary sense an infectious fever? (a) No cases have so far been recognised in which direct infection from another person ill of the disease could be scientifically established. (b) The outbreaks are at different points of the city with no history of infection. (c) All the methods adopted—that is, isolation of patients in the fever hospital and disinfection—have failed completely in arresting the disease. (d) At the various hospitals where cases have been treated, no nurse, medical officer, or attendant has been attacked, a state of matters altogether different from that which would occur had cases of typhus fever or small-pox (without vaccination) or scarlet fever been introduced in the same way. (e) Dublin is only a three hours' journey from Belfast with a constant interchange of people: why is Dublin escaping and Belfast suffering so terribly with this strange disease? 2. The necropsies so far would support the view that the disease was swallowed, just as typhoid fever generally is, rather than that the disease germs on the German view entered the brain centres through the ethmoid from the nose. 3. May it not be that the disease germs (the meningococci) are always with us but that the peculiar atmospheric conditions have done one of two things: made patients, through catching cold, influenza, &c., more vulnerable (increased susceptibility); or has the strange, cold, variable weather made the bacilli more infective? 4. It is remarkable that all the adults attacked (and a young man of the better classes died this week at one of the Belfast suburbs called the Knock) have been almost entirely men. Why, so far, are adult women escaping? We are groping in the dark so far as to the nature of this peculiar disease, but light will come.

Feb. 26th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Prevention of Tuberculosis.

A MEETING of the International Society for the Prevention of Tuberculosis (*Société Internationale contre la Tuberculose*) was held on Feb. 5th when various resolutions were adopted. The first discussion arose in connexion with a communication by M. Glaisse on the subject of the sanitation of the small court-yards (*courrettes*) which may be in connexion with high buildings. The atmosphere of these places was liable to become septic, fetid, and stagnant. It might be purified by filtering the air through a spray of water and free ventilation sufficient for the prevention of bad smells could be provided if some slight modifications were made in the existing arrangements. M. Bernheim said that the best remedy for the evils complained of was to take care that these places were not too much closed in. M. Juillerat suggested that dispensary medical officers should coöperate with the compilers of the sanitary register of houses (*casier sanitaire des maisons*) by giving information as to the houses where the tuberculous dispensary patients resided. Dr. Georges Petit and Dr. Thézard communicated a paper on the use of asparagin in medicine. They had been making experiments with nutrient media for the preparation of bouillon intended for the cultivation of microbes, and in the course of this inquiry it occurred to them that asparagin associated with phosphoric acid and with various phosphates might be useful therapeutically. Clinical observations subsequently showed that asparagin promoted assimilation and might be of great service in the treatment of tuberculosis, anaemia, and various cachexias. Patients who had for a long time suffered from total loss of appetite were by this means enabled to take their food well and consequently increased in weight. Asparagin is given in doses of one or two grammes daily before the two principal meals; it is taken in alkaline or

acid solutions according to the state of the patient's stomach.

Lumbar Puncture in the Complications of Suppurative Otitis.

At a meeting of the Society of Surgery held on Feb. 6th M. Leguen read an account of a case which had been under the care of M. Lapointe. The patient had suffered from suppurative in the middle ear for some years but shortly before his entry into the hospital had complained of headache, feverishness, and stiffness of the neck. M. Lapointe opened the antrum and the tympanum, enlarged an opening which he found in the upper wall of the tympanum, and evacuated a subdural abscess. The dura mater itself was intact. Nevertheless M. Lapointe, struck by the extreme polynucleosis which a lumbar puncture revealed, resolved to open the dura mater. Another abscess came into view which was drained and the patient made an uneventful recovery.

A Drug Eruption.

M. Bergé read this case before the Hospitals Medical Society at a meeting held on Feb. 22nd. The patient was suffering from acute bronchitis and after taking a medicine containing opium developed a typical scarlatiniform rash which terminated in an intense desquamation. The appearance of the eruption coincided with the disappearance of the bronchial catarrh. During the night, however, the patient was troubled again with pulmonary symptoms and took some more of the medicine as he found that it always gave him great relief. The rash appeared for the second time.

"Le Théâtre Antisérielien."

M. G. Le Vallier and M. P. Nigel have recently organised a quite novel series of evening entertainments with a view to support and to carry on the movement for the prevention of venereal diseases. The programme will include: (1) a dramatic performance in two acts—*L'Immolee*—founded on a case of sterility due to syphilis; and (2) a demonstration of the effects of syphilis exhibited by lantern pictures, according to the most recent practical observations. The entertainments in question (*soirées populaires*) commenced on Feb. 22nd at No. 133, Rue Saint Denis, and the management provide members of the medical profession with free admission and fauteuils on presentation of their cards.

Feb. 25th.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Syphilis Antitoxin in the Cerebro-spinal Fluid.

Professor Wassermann and Dr. Plant, writing to the *Deutsche Medizinische Wochenschrift*, announce that they have discovered an "antistoff" of syphilis in the cerebro-spinal fluid of patients suffering from dementia paralytica. Their experiments were based on a discovery made by Professor Wassermann—namely, that the hæmolysis of red corpuscles is hindered when an "antistoff" is mixed with a fluid containing a toxin. In experiments with 41 samples of cerebro-spinal fluid the hæmolysis ceased in 32 when they were mixed with an extract of syphilitic organs. Neither the cerebro-spinal fluid alone nor the syphilitic extract alone hindered the hæmolysis, and the effect was not produced when the fluid was brought in contact with tissues obtained from a person free from syphilis. It is therefore proved that anti-syphilitic substances are formed in the cerebro-spinal fluid of the majority of cases of dementia paralytica—in other words, it is proved that these patients have formerly suffered from syphilis. Professor Wassermann and Dr. Plant, however, decline to say that the question whether this disease is really caused by syphilis is decided by these experiments.

Sick Clubs and their Medical Officers.

The medical officers of a sick club at Cologne had on the advice of the medical union resigned their appointments without giving notice of their intention, so that the members of the club were for some time left without medical attendance. The club accordingly brought an action for damages against five of the medical men and the decision of the court was to the effect that their course being illegal they were bound to indemnify the club. The club now demands not less than 100,000 marks (£5000) from the defendants but another court will have to decide whether this sum really represents the loss which the club has sustained by the sudden resignation of the medical men. This action will

association and the new rules were sent to England to the council and a cable was received which was supposed to sanction the arrangement. Accordingly the annual meetings of the two societies were held conjointly on Jan. 4th and the following new office-bearers were elected under the new rules: President: Professor Harry B. Allen. Vice-Presidents: Mr. G. A. Syme and Mr. George Cuscaden. Treasurer: Dr. O. H. Mollison. Honorary secretary: Dr. L. J. Balfour. Librarians: Mr. A. W. F. Noyes and Dr. H. D. Stephens. Council: Dr. W. R. Boyd, Dr. G. T. Howard, Dr. Felix Meyer, Dr. W. Moore, Mr. F. W. W. Morton, Mr. W. Beattie Smith, Dr. J. F. Wilkinson, and Dr. A. J. Wood. All of these, except the President and Vice-Presidents, were the officers of the Medical Society of Victoria. Professor Allen has taken the leading part in the negotiations which led to the amalgamation and in drafting the scheme for union. Mr. Syme was president of the Victorian branch in 1900 and resigned with all its other members of the council and many of the branch when the branch did not ratify by a three-fourths majority the action of the council in expelling a member. Mr. Cuscaden was the retiring president of the branch and the only member of the late council of the branch re-elected.

Hospital Affairs.

The new Royal Alexandra Hospital for Children, Sydney, was officially opened by his Excellency the State Governor on Dec. 12th, 1906. It is situated at Camperdown, and will accommodate 175 children when complete. It is claimed to be one of the finest, if not the finest, children's hospital in the world. Immediately connected with the receiving and examination rooms there is a special pavilion containing four separate small wards of eight beds each, in which patients will be placed for the necessary few days following their admission, to insure their having no latent infectious disease, before their being transferred to the main pavilions, thus preventing the risk of infecting the larger wards should any such contingency arise. There are two main medical and surgical pavilions, both of which, as well as the special pavilion, are flanked by very spacious verandahs and balconies, capable of containing a row of cots and so of being utilised for sleeping out, for which further provision has been made by wide doorways from the wards to each between every pair of cots, so that they may be wheeled out.—It has been once more proposed to remove the Melbourne Hospital from its present site to one farther from the centre of the city. The proposal was first made 20 years ago but the site then suggested, the horse and pig market near the university, could not be obtained. The same site is now once more suggested. It is further proposed to remove the town hall to the present site of the hospital. The idea is that the sale of the present town hall site would furnish sufficient funds to purchase the hospital site and to rebuild there, and the purchase money of the hospital site would enable the hospital authorities to rebuild the institution in the market, and the Government is expected to grant a new site farther out still for the market. Opinions are divided as to the advisability of the proposals. The decision of the whole question will rest with the city council.—The Women's Hospital, Melbourne, has at last decided to undertake the care of women not admitted to the institution and to provide medical attendance and nursing to indigent obstetric cases in their own homes within a certain area.—Some time ago Mr. T. Scott published statements to the effect that the Warrnambool (Victoria) Hospital was imposed upon by persons who could afford to pay for private medical attendance. The committee invited Mr. Scott to prove his statements and placed the books of the hospital at his disposal. He accepted the challenge and recently wrote to the committee saying that after going through the books he found the names of 40 persons who, in his opinion, were not entitled to admission on the ground of inability to pay private fees. The committee, however, held that the cases referred to, with one exception, admitted in error, were suitable cases for admission.—At a recent inquest on a patient at the Melbourne Hospital a question was raised of some importance to medical men. The patient was admitted with septicaemia after miscarriage. The resident surgeon gave a certificate of death and the body was on the way to the cemetery when the burial was stopped by order of the coroner, who directed the making of a necropsy which showed that death was due to peritonitis and septicaemia, but there was nothing to indicate that anything of a criminal nature had occurred. The coroner,

however, said that he was of opinion that abortion had been illegally procured and if the case had been differently managed by the hospital authorities the unknown author of the act might have been discovered. In every case of the kind the police should receive full information from the medical man in attendance.

Supervision of Private Hospitals.

The Select Committee of the Legislative Council of New South Wales appointed to inquire into the Private Hospital Bill has taken a good deal of evidence which points to the necessity for legislation on the subject. It was stated that 450 lying-in homes existed in the State and that many were in charge of ignorant, incapable, and often drunken women. Cases were cited where a woman had a patient waiting for confinement and the only room available for the lying-in was occupied by a patient with typhoid fever. In another instance a nurse had a case of erysipelas in the home and was at the same time attending four maternity patients in the town. 85 per cent. of the parish hospitals were lying-in homes and malpractice was rife in them.

Training of Mentally Defective Children.

At the last meeting of the Board of Public Health of Victoria the question of establishing a special training school for mentally defective children was considered. The chairman, Dr. Norris, observed that while everyone would recognise the wisdom of such a proposal he thought that it should be accompanied by some legislative enactment to prevent mentally deficient persons who received the benefit of such work, from marrying. Special treatment, while not abolishing the deficiency, might so improve the condition of the subjects that they might find it easier to marry and to transmit their hereditary deficiencies. The Board agreed with this view and the chairman was instructed to communicate it to the Chief Secretary.

A Retreat for Inebriates.

The Government of Victoria has authorised the purchase of an estate at Lava, with an area of 600 acres, for the purpose of establishing an inebriate retreat.

Deplorable Accident with a Pistol.

Dr. Andrew Davidson, medical superintendent of the Callan Park Asylum for the Insane, will receive great sympathy in peculiar circumstances. A patient had somehow procured a revolver and Dr. Davidson sent for the plumber to the institution to force the locks of the patient's boxes. He did so, and found in one of them a revolver which he handed to Dr. Davidson. Almost immediately the revolver went off and the plumber was shot fatally.

Adulteration of Milk and Butter.

Heavy fines were recently imposed in the central police court, Sydney, for adulteration of milk. There were 11 charges brought against one company trading in several suburbs. The analyses showed that the amount of added water varied from 6.75 to 21 per cent. The defendant had been convicted previously and his employers had been fined on 47 occasions.—The city analyst at Perth, Western Australia, has published a report on food-supply—chiefly milk, butter, and tinned foods. The butter he found much adulterated, oleo-margarine, fats, and oils being skillfully combined in it, and preservatives freely used. Tinned foods were invariably bad or inferior from decomposition.

Prosecution of the Vendor of an Alleged Cure for Consumption.

An agent was committed for trial at the Sydney police court on Jan. 8th for obtaining money by false pretences. He sold an alleged cure for consumption called "Tuberculozque." An analysis showed that the preparation, which was sold in two bottles, No. 1 and No. 2, consisted of a dilute solution of bromide of potassium in (1) and a dilute solution of a salt of iron in (2). The agent alleged that the preparation contained copper.

Dinner to Dr. R. R. Stawell.

On Jan. 15th Dr. R. R. Stawell, physician to the Children's Hospital and to out-patients at the Melbourne Hospital, was entertained at dinner by a large and representative gathering of his medical brethren prior to his departure for a visit to Europe. Sir Thomas FitzGerald presided and proposed Dr. Stawell's health, the toast being supported by Mr. M. U. O'Sullivan and Mr. G. A. Syme. Dr. Stawell, in replying, after some personal reminiscences in which he acknowledged the help and loyalty of his hospital colleagues, referred to

as to discipline, as well as to permit the College to make pecuniary grants to medical societies.

A Hygienic Institute for London, Ontario.

The Ontario Government has decided to make a grant of \$50,000 to the Medical Faculty of the Western University at London, Ontario, for the purpose of a hygienic institute in that city. A sum of \$5000 per annum will also be given for five years for its maintenance. As it is the policy of the present Government to encourage medical education in other sections of the province of Ontario than that immediately associated with the Provincial University at Toronto, this procedure is therefore in accordance with that policy. The city of London will give a free site for the institution and will also devote a sum equalling that of the Government to the erection of the building. The city will also erect a new contagious diseases hospital to be worked in connexion with the institute. The latter will be a great benefit to the medical men practising in Western Ontario.

Ontario Medical Council and the Canadian Press Association.

The Canadian Press Association has just finished its annual sitting in Toronto. As during the session of last year, this association has placed itself on record as being antagonistic to the Ontario Medical Council as well as to all similar bodies, which it claims are conducted by irresponsible men. The reason for the antagonism of the Press Association is not far to seek. Recently the Ontario Medical Council had before it the case of a practitioner who advertised a remedy alleged to cure *la grippe* and other bodily ills. He was found guilty of misconduct from a professional aspect and his name was ordered to be expunged from the Ontario Register. The matter was, however, taken into the courts and the name was ordered to be replaced on the Register. The disinclination of practitioners generally to advertise does not, of course, meet with the approval of the Press Association. Their action, therefore, smacks decidedly of interestedness.

New Nurses' Home Opened in Toronto.

A fine new nurses' home for the nurses of the Sick Children's Hospital, Toronto, has just been completed and opened with appropriate ceremonies. It was the gift of Mr. John Ross Robertson, the proprietor of the *Evening Telegram*, Toronto, and cost \$130,000. Mr. Ross Robertson has done a great deal for this institution. He originally gave a large sum of money for the hospital and then presented to the institution the Lakeside Home for Sick Children on Toronto Island, which is said to be the largest home or hospital for summer residence in the world. The hospital has cared for 75,000 children since the day of its establishment.

Gift to the University of Toronto on the Nobel Plan.

A prospector at Sudbury, Ontario, recently died and left to the University of Toronto \$10,000 of Ontario Government bonds, the interest of which is to be used in giving small prizes similar to the Nobel prizes. Two of the clauses of the will are of interest to the medical profession as well as to others in Canada. A prize is to be given for any important discovery, invention, or development by any Canadian which will lessen the dangers and loss of life in connexion with the use of electricity in supplying power and light, and another for any marked public distinction achieved by any Canadian in scientific research in any useful and practical line.

The Verdun Hospital, Quebec.

The annual meeting of the board of management of the Protestant Hospital for the Insane at Verdun, province of Quebec, was held in Montreal a few days ago, when Dr. Burgess, the medical superintendent, presented the annual report. This stated that 503 patients were in residence in the hospital on Jan. 1st, 1906. During the year 151 patients were admitted (87 men and 64 women), 110 were discharged, 34 died, and one escaped. At the close of the year there were 507 in residence. It cost \$114,860 to carry on the institution during the year. The receipts were \$112,182.

"Osteopaths" in Ontario.

The province of Ontario possesses a few of those citizens of the United States who now and again come into Canada for the purpose of exploiting some peculiar methods in the practice of quackery. Of these there is a body known as the "osteopaths," who now seek incorporation in the College of Physicians and Surgeons of Ontario, practically on the same basis as the homeopaths—that is to say, they desire representation on the Ontario Medical Council and licence and power to conduct their own examinations and to confer

their own degrees. It is a little presumptuous but quacks are never deficient in that qualification.

Notes from Winnipeg, Manitoba.

The *Western Canada Medical Journal* has appeared at Winnipeg. Two numbers have been issued. Dr. W. Osler contributed the opening article to the first, and the opening article of the second is from the pen of a layman on "The Effect of Sunlight upon White Skin." It is a decidedly interesting and able article.—The College of Physicians and Surgeons of Manitoba is having a plebiscite taken on the subject of reciprocity with the other provinces of the Dominion.—The Manitoba Government has promised to grant \$25,000 for the purposes of a consumption sanatorium when the committee in charge of the matter has raised \$50,000. The sum of \$15,000 has already been raised.—The Manitoba Medical College at Winnipeg has entered its new building. There are 140 students in attendance, 35 being in their first year.—The following are the officers of the Winnipeg Medical Society for the current year: President, Dr. E. W. Montgomery; Vice-President, Dr. J. R. Davidson; Second Vice-President, Dr. N. J. McLean; secretary-treasurer, Dr. O. H. Vrooman; and councillors, Dr. McKenty, Dr. H. MacKay, Dr. H. P. H. Galloway, and Dr. J. O. Todd.

Ontario Medical Council.

The following medical practitioners in the province of Ontario will constitute the Ontario Medical Council for the next four years:—Elected by acclamation: Dr. J. L. Bray, Chatham; Dr. J. McArthur, London; Dr. J. A. Robertson, Stratford; Dr. J. Henry, Orangeville; Mr. P. Stuart, Milton; Dr. S. H. Glasgow, Welland; Mr. E. E. King, Toronto; Dr. H. Bascom, Uxbridge; Dr. S. O. Hillier, Bowmanville; Dr. A. F. MacColl, Belleville; Dr. W. Spankie, Wolfe Island; Dr. J. W. Lane, Mallorytown; and Dr. M. O. Klotz, Ottawa. By election: Dr. J. H. Cormack, St. Thomas; Dr. T. W. Vardon, Galt; Dr. R. J. Gibson, Sault, Ste. Marie; and Dr. J. S. Hart, Toronto. The homeopathic representatives are Dr. G. Henderson, Strathroy; Dr. L. Luton, St. Thomas; Dr. E. T. Adams, Toronto; and Dr. C. E. Jarvis, Toronto.

Feb. 18th.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

Bubonic Plague.

AFTER a long interval two fresh cases of plague have occurred in Sydney. Both the patients were employed near the harbour and are mild cases. Three rats infected with plague were caught in the neighbourhood of one of the cases. A case has also occurred in Queensland.

Prevalence of Disease in Victoria.

At the last meeting of the Board of Public Health of Victoria the chairman, Dr. W. P. Norris, gave a review of some statistics as to the prevalence of certain diseases. During the fortnight ending Dec. 29th, 1906, there were 39 cases of typhoid fever, 31 cases of diphtheria, and three of scarlet fever reported. The average for the corresponding period of the years 1902 to 1905 was 89 cases of typhoid fever, 96 of diphtheria, and 50 of scarlet fever. From the year 1904 there had been a decline in the prevalence of typhoid fever; pulmonary tuberculosis had increased, the figures being 400 cases in 1904, 550 cases in 1905, and over 700 in 1906. The number of deaths, however, had been reduced. From 1901 the yearly mortality from pulmonary tuberculosis had been 701, 704, 681, 626, and 601. The population had increased and the rate per 10,000 of the population was in the same years 14.3, 14.0, 13.5, 12.2, and 11.7. The sanatorium for consumptives since its establishment 20 months ago had treated 276 patients, of whom 177 were discharged with the disease so arrested that they could return to work, 35 had been unrelieved, two had died, and 62 remained in the institution.

Amalgamation of the Medical Society of Victoria and the Victorian Branch of the British Medical Association.

As stated in a former communication, the Medical society of Victoria has become associated with the Victorian branch of the British Medical Association, subject to the approval of the central organisation of the British Medical Association in England. The terms of the proposed combined

and a monograph on Ambrose Paré.—Dr. Jentz, professor of gynaecology in the University of Geneva.—Dr. Eugen Plessin of Berlin, a strenuous advocate for the adoption of animal vaccine.

THE EIGHTIETH ANNIVERSARY OF LORD LISTER'S BIRTHDAY.

THE eightieth anniversary of Lord Lister's birthday occurs in April next, and it has been suggested that the event would suitably be commemorated by the republication of his scientific papers prefaced by a short biography. The biography would contain an account of the part played by the genius of Lister in the development of our knowledge of infectious processes and the history of his efforts to obviate wound infection, his work in these directions having revolutionised the whole of surgical practice and led to the saving of more lives and the prevention of more misery than it is possible to calculate. Lord Lister's original papers, which are scattered throughout the medical and scientific publications of this country, are for the most part accurate observations of his personal labours which gives them a particular value from the biographical point of view. We feel sure that a very large number of professional and scientific men, whatever their country or school, will be glad to have the collected works of Lord Lister. It may be added that already a number of Lord Lister's friends and admirers have expressed their warm approval of this means of celebrating his birthday, and it is proposed to form a committee representative of medicine and science to determine how the above object can best be attained. Dr. C. J. Martin of the Lister Institute will be glad to hear of the names of any who wish to take part in this tribute to one who for 40 years has been pre-eminent among the surgeons of the world.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—The Gillson Scholarship in Pathology for 1907 has been awarded to Mr. Francis Arthur Bainbridge, M.A., M.D. Camb., D.Sc. Lond., M.R.C.P. Lond., of Guy's Hospital. At examinations held recently the following candidates passed in the subjects indicated:—

Surgery.—M. B. S. Button (Sections I. and II.) and O. C. Morrell (Section I.), London Hospital; W. V. Pegler (Section II.), Leeds; E. W. Squire (Sections I. and II.), St. Mary's Hospital; and J. S. Ward (Sections I. and II.), Sheffield.
Medicine.—M. B. S. Button (Sections I. and II.), London Hospital; E. S. Cooke (Sections I. and II.), Royal Free Hospital; S. F. Fouracre (Sections I. and II.), Charing Cross Hospital; S. Singh (Section II.), Glasgow; and G. L. Walker (Sections I. and II.), Leeds.
Forensic Medicine.—M. B. S. Button, London Hospital; J. C. Fletcher, Royal Free Hospital; S. F. Fouracre, Charing Cross Hospital; G. Rolason, Birmingham; and R. Spears, University College Hospital.
Midwifery.—H. J. W. Barlee, Middlesex Hospital and Lyons; M. B. S. Button, London Hospital; S. F. Fouracre, Charing Cross Hospital; S. Singh, Glasgow; and R. P. Wyld, Manchester.
The diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery: M. B. S. Button, W. V. Pegler, and S. Singh.

UNIVERSITY OF OXFORD.—In a congregation held on Feb. 16th the following degrees in medicine were conferred:—

Doctor of Medicine.—A. M. Gossage, Magdalen College.
Bachelor of Medicine and Surgery.—L. T. Barra, University College.
On Feb. 19th a statute was passed in convocation empowering the Board of the Faculty of Medicine to send two representatives as members of the Board of Studies for Responses.

UNIVERSITY OF CAMBRIDGE.—Dr. Laurence Humphry has been appointed a member of the degree committee of the special board for medicine.—Dr. Rouse, Mr. O. Browning, Mr. J. Wallis, Mr. E. A. Parkyn, and Mr. D. H. S. Cranage have been appointed delegates to the International Congress on School Hygiene, to be held in London next May.—Mr. F. Darwin, M.A., M.D., has been appointed to represent the University at the 200th anniversary

of the birth of Linnaeus, to be held at Upsala in May next.—The following have been appointed electors to professorships in the University:—Anatomy: Professor Howard Marsh and Professor A. Thomson. Downing of Medicine: Sir Thomas Barlow and Sir E. O. Perry. Botany: Professor Langley. Zoology: Dr. W. H. Gaskell and Professor Graham Kerr. Physiology: Professor Sherrington and Dr. H. K. Anderson. Surgery: Dr. L. Humphry. Pathology: Professor G. H. F. Nuttall.—At a Congregation on Feb. 14th the following degrees were conferred:—

M.C.—H. M. Davies, Trinity.
M.B.—O. M. Stevenson, St. John's; and E. E. Atkin, Gonville and Caius.

The collections in the Museum of Zoology have been enriched by gifts of a cast of the skeleton of the gigantic marsupial *Diprotodon australis* by Dr. E. C. Stirling, F.R.S., of Adelaide, and of skeletons, skulls, and skins of antelopes from Florida and tropical Africa by Mr. O. B. C. Storey.—Mr. J. J. Lister, St. John's, has been appointed a manager of the Balfour Fund for Animal Morphology in the place of the late Sir Michael Foster, K.C.B.—Mr. F. A. Potts, Trinity Hall, is to occupy the University table in the Marine Biological Association's Laboratory at Plymouth.

UNIVERSITY OF LONDON.—At examinations held recently the following satisfied the examiners:—

B.Sc. DEGREE BY RESEARCH (FOR EXTERNAL STUDENTS).
Chemistry.—Thomas Stewart Patterson, University of Leeds; and Kenworthy James Thompson, University College, Aberystwith.
Geology.—Lewis Leigh Fennor, Laboratory of the Geological Survey of India, Calcutta.

ROYAL COLLEGE OF SURGEONS IN IRELAND: FELLOWSHIP EXAMINATION.—The following candidates, having passed the necessary examination, have been admitted Fellows of the College:—

John Armstrong, B.Ch., &c., Royal University, Ireland; Samuel Creighton Clarke, L.R.C.S.I., &c.; Raghunath Vithal Khedkar, L.R.C.S.I., &c., Edin.; George Whitfield Little, L.R.C.S.I., &c.; Augustus Anson Warren Merrick, L.R.C.S.I., &c.; and Francis James Palmer, L.R.C.S.I., &c., Captain, R.A.M.C.

The following candidates have passed the primary part of the Fellowship examination:—

Burjorji Pirozsha Ranaji, L.M. and S., Bombay University; Patrick Edward Hayden, L.R.C.S.I., &c.; Henry Stokes, B.Ch., &c., University, Dublin; Robert Adams, Miss Ina Marion Clarke, Ernest Cotton Deane, Frank Newenham Harvey, Noel Morley Herbert, John Joseph McGrath, John Menton, Miss Amy Florence Nash, George Guming Sneyd, Miss Cecilia Forence Williamson, and Owen Waller James Wynne.

FOREIGN UNIVERSITY INTELLIGENCE.

Bonn: Dr. Hermann Kuhn of Königsberg has been appointed Professor of Ophthalmology in succession to Professor Theodor Saemisch who has retired; Dr. H. Stursberg has been recognised as *privat-docent* of Internal Medicine.—**Brussels:** A School of Tropical Medicine will be opened next autumn and will pay special attention to sleeping sickness; Dr. van Kampenout has been appointed Director.—**Gießen:** Dr. Voß of Basle has declined the chair of Medicine.—**Heidelberg:** Dr. Otto Benda has been recognised as *privat-docent* of Anatomy.—**Jena:** Dr. Giese, *privat-docent* of Forensic Medicine, and Dr. Lommel, *privat-docent* of Medicine, have been appointed Extraordinary Professors.—**Kiel:** The chair of Ophthalmology which Professor Völcker is resigning has been offered to Professor Otto Schirmer of Greifswald.—**Königsberg:** Dr. Otto Voss, *privat-docent* of Otolaryngology, has been granted the title of Professor.—**Munich:** Dr. Ernst Moro of Graz has been recognised as *privat-docent* of Children's Diseases and Dr. M. Geiger as *privat-docent* of Psychology.—**Prague (German University):** A chair of Experimental Morphology and one of Laryngology are about to be established.—**Tomsk:** Dr. Wedenski has been appointed Professor of Surgery.—**Turin:** Dr. Teobaldo Soli has been recognised as *privat-docent* of Midwifery and Gynaecology.—**Würzburg:** Dr. Enderlen of Basle has been appointed Professor of Surgery in succession to the late Professor Schönborn.

DONATIONS AND BEQUESTS.—The honorary secretaries of King Edward's Hospital Fund for London have received the sum of £10,000 from the executors of the late Mr. John Nicholas.—The late Mr. James Bownick Davison has bequeathed, subject to his wife's life interest, £1000 to King Edward's Hospital Fund and £500 to the Sarbiton Cottage Hospital.—By the will of Mrs. Harriet Venables the Infant Orphan Asylum at Slough will receive £500. The

the necessity and importance of moving the Melbourne Hospital and increasing its departments and usefulness.

Honour conferred on Dr. A. L. Kenny.

Dr. A. L. Kenny of Melbourne, who is on a visit to Europe after travelling in the East, has been appointed private chamberlain to the Pope, with the title to wear cape and sword and to rank with noblemen on duty at the Vatican. Dr. Kenny is on the staff of St. Vincent's Hospital. He acted as secretary to the Australasian Roman Catholic Congress. Jan. 21st.

Obituary.

EBENEZER TOLLER, M.R.C.S. ENG., L.S.A.

Mr. Ebenezer Toller, who recently died at his residence, "The Zephyrs," Scarborough, after a long and painful illness, was descended from a remarkable Bedfordshire family, his grandfather and three great-uncles being each between 7 and 8 feet in height, and his four great-aunts are described on an old engraving held in the family as the four beauties of Bedfordshire. During his infancy his father died suddenly whilst speaking at a public Whig meeting at the time of the Reform Bill, his mother dying shortly afterwards. Mr. Toller studied medicine at King's College Hospital and took the diplomas of M.R.C.S. Eng. and L.S.A. in 1857 and 1858 respectively. On leaving King's College he at once became resident medical officer to the St. Andrew's Castle Private Asylum, Bury St. Edmunds, and from here he went to the Middlesex County Asylum at Colney Hatch; he was afterwards appointed medical superintendent of St. Luke's Lunatic Hospital, London, and the ability shown by him in his management there obtained for him the similar post at the Gloucester County Asylum, which he held from 1863 to 1882. This asylum had been built up gradually from a comparatively small structure to one holding rather less than 600 patients, but the demand for further accommodation made it necessary to build a branch asylum to accommodate 400 more patients on a site about a mile farther from the city. The extra work and anxiety which this expansion involved unfortunately proved so great a strain for Mr. Toller that his health completely broke down and he was compelled to retire. He was the pioneer in providing in lunatic asylums those entertainments which are now looked upon as a matter of course in every asylum. His musical ability prompted him, when a medical officer at Colney Hatch Asylum, to institute concerts for the patients. These and other forms of entertainment which he organised attracted great attention and received the recognition of the Commissioners in Lunacy so far back as March, 1862. At St. Luke's Hospital the assistance rendered by his many musical friends gave his concerts a character of more than average importance. Mr. Toller was also a strong advocate of treating the insane in surroundings as homelike as possible and deprecated strongly their being kept in large numbers in great buildings. These views he brought before the Association of Medical Officers of Asylums at the Royal College of Physicians of London in 1864, in a paper which was afterwards published with plans of cottage asylums. He was a Fellow of the Royal Meteorological Society and at Gloucester he made systematic meteorological observations which were forwarded monthly to Greenwich Observatory. He was also to be seen in the hunting field and played cricket in the asylum eleven. His second son, Dr. Seymour Graves Toller, became assistant physician to St. Thomas's Hospital, but his health failing he was appointed physician to the Government Hospital at Cairo and lecturer in medicine. Here he died suddenly and in the absence of any relatives (in consequence of their inability to arrive in time) his funeral was attended by Lord Cromer as principal mourner. A children's ward at St. Thomas's Hospital bears his name as a memorial and the "Seymour Graves Toller prize" is awarded annually to the first student in medicine. Dr. S. G. Toller was a brilliant violinist and a member of the Royal Amateur Orchestral Society. Mr. E. Toller had four other sons but only the eldest survives him. The funeral service was held at Holy Trinity Church, Scarborough, of which he was a churchwarden, and it was attended by a large number of the residents.

JOHN FALCONER, M.R.C.S. ENG.

Mr. John Falconer of Lasswade, near Edinburgh, who died on Jan. 6th at the age of 80 years, was a man whose genial personality will live in the memories and thoughts of all who knew him. The son of a well-known practitioner in Loanhead, he naturally received his education in Edinburgh and while studying medicine at the University there he became demonstrator to Professor John Goodieir. He took the diploma of M.R.C.S. Eng. in 1848 and for a time was assistant to Professor Quekett, the London histologist. He had many anecdotes of Goodieir, for whom he cherished a deep admiration, as well as of Sir Richard Owen the anatomist, and various London surgeons. During the Crimean war he did duty in the Turkish Hospital at Scutari. Soon after returning to England he went to China, where he practised at Han-kau for 17 years. At the end of this time he suffered from inflammation of the liver, from which he made a slow recovery. Being in easy circumstances he settled near Lasswade, where he could indulge his favourite pursuit of horticulture. Mr. Falconer was a man of ferid character and powerful build. He excelled in athletic exercises. A man of lively aesthetic tastes, he was warm and enduring in his friendships, keen in his resentments, easily accessible to pity, generous, and charitable. He was a zealous Freemason, being a past master of the Celtic Lodge and having held high office. About a year ago Mr. Falconer had a slight paralytic shock which recurred several times, much impairing the power of the right side and lessening the vigour of his mental faculties. His only son, John James Falconer, who had studied medicine at Edinburgh for several years and had passed all the examinations save the concluding ones, died from consumption three weeks before his father.

ROBERT A. L. GRAHAM, M.B., B.Ch., B.A.O. R.U.I.

Dr. R. A. L. Graham of the Belfast District Lunatic Asylum, who died on Feb. 13th from perforation of the bowel during an attack of typhoid fever, was one of the ablest of the younger members of the Belfast School of Medicine. The son of a Presbyterian clergyman (the Rev. Dr. Graham of Comber, county Down), young Graham when a student was at Queen's College, Belfast, where, as well as in the Royal University of Ireland, he had a brilliant record. In addition to being a prizeman in many classes, he was senior scholar in biological science at Queen's College. In the Royal University he obtained the degree of B.A. in 1896, taking honours and an exhibition, and in 1898 he graduated as M.B., B.Ch., and B.A.O. At the University he was also awarded in 1899 the diploma in mental diseases, and in the following year he won the Stewart scholarship in mental diseases (£200). After graduating in medicine he studied in London, Freiburg, and at Munich. He was a skilled pathologist and was demonstrator of pathological neurology in Queen's College, Belfast. For the past nine years he had been assistant medical officer at the Belfast Asylum in Grosvenor-road. Up to the time of his falling ill—three weeks before his death—he had been collecting information for the Royal Commission on the Care and Control of the Feeble-Minded, with special reference to mentally feeble children in and around Belfast. Through his enthusiasm a small but thoroughly equipped laboratory had been fitted up at the asylum, where he did much original work, and one of his most interesting contributions to the local medical society was on a case of General Paralysis of the Insane with Syphilitic Meningomyelitis, the paper being afterwards published in the *Journal of Mental Science*. He was specially complimented by the Commissioners in Lunacy for his efforts to raise the pathological side of asylum work. Dr. Graham was 31 years of age and unmarried. A modest kindly man, he had all the enthusiasm of the man of science and the thoroughness of the careful investigator and close observer.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.—The deaths of the following eminent foreign medical men are announced:—Dr. L. Willems, formerly President of the Belgian Academy of Medicine.—Dr. G. Doremberg of Cannes, corresponding member of the Academy of Medicine of Paris.—Dr. Karl von Lotzbeck, surgeon-general in the Bavarian army, who has been on the retired list for more than 11 years. He published various surgical papers

ASHLEY and Mr. COURTHOPE have given notice that they will move the rejection of this measure.

Butter and Margarine Bill.

The Bill which Sir EDWARD STRACHEY has introduced into the House of Commons to make further provision with respect to the manufacture, importation, and sale of butter, margarine, and similar substances has been printed. It contains clauses for the registration and inspection of butter factories and for the prohibition of adulterants on these premises. The inspection of these factories is placed in the hands of officers of the Board of Agriculture and of officers of local authorities who are authorised to procure samples under the Sale of Food and Drugs Act. Clause 4 of the Bill imposes a limit of moisture. No butter in any butter factory must contain more than 16 per cent. of water and a like standard is set up for margarine. If that limit is exceeded the occupier of the factory or the consignor of the butter or the margarine shall (whether the excess of moisture is due to adulteration or not) be guilty of an offence under the Act unless he proves to the satisfaction of the court that the butter or margarine was not made, blended, reworked, or treated in the factory. Any person who manufactures, sells, or exposes for sale, or has in his possession for the purpose of sale, any butter substitute which contains more than 24 per cent. of water will also be guilty of an offence under the Act. These limits of moisture are applied in another clause to imported butter, margarine, and butter substitutes.

Medical Inspection and Treatment of School Children.

The Education Acts (Amendment) Bill introduced by Mr. WALTER REA contains a provision for the medical inspection of school children. Under this Bill a local education authority would be empowered "to provide for the medical inspection of children before or at the time of their admission to a public elementary school and on such other occasions as the Board of Education direct." It would also have the power to make such arrangements as might be sanctioned by the Board for attending to the health and physical condition of the children educated in public elementary schools.

Coroners' Inquests.

Mr. LUKE WHITE has presented a Bill in the House of Commons which is designed to dispense with the compulsory viewing of bodies on the holding of coroners' inquests.

The Sale of Whisky Bill.

The Bill, which has been presented in the House of Commons by Mr. WILLIAMSON, for the purpose of amending the law relating to the Sale of Whisky and to provide for the marking of casks and other vessels containing whisky, has been printed. It is backed by Mr. MURRAY, Mr. CATHCART WASON, Sir ANDREW TORRANCE, and Mr. BILLSON. The provisions of the Bill are summarised in a memorandum, the most important being as follows: To secure to purchasers of whisky a clear statement whether it is a whisky made in a pot still from pure malt, or of malt and corn, or is in part a spirit made in a patent still from unmalted grain. To carry out this object the Bill proposes to enact that all whisky shall, from the time of leaving the distillery till sold to the consumer, be described by a mark or label on the cask or bottle as "whisky" or "blend of whisky and patent still spirit," as the case may be. Provision is made for similar information being given to persons purchasing whisky on draught. Power to prosecute for offences against the Bill is given to officers of Inland Revenue, but persons authorised by local authorities having the execution of the laws relating to food and drugs are also to have power to prosecute and are to be supplied by the Inland Revenue with the information necessary for that purpose.

Infant Life Protection Bill.

Mr. STAVELTY HILL's Bill to amend the Infant Life Protection Act, 1897, is supported by Sir JOHN KENNEDY, Mr. ARTHUR LEE, Mr. HAY, Mr. WALBROND, Mr. RAMSAY MACDONALD, Mr. HILLS, and Mr. NICHOLLS.

The Government's Pharmacy Bill.

On Friday Mr. HERBERT SAMUEL presented to the House of Commons a Bill promoted by the Home Office to regulate the sale of certain poisonous substances and to amend the Pharmacy Acts. A Bill introduced by Mr. WESTREY to amend the Pharmacy Acts has also been printed. It provides, *inter alia*, that every shop for the sale of poisons "shall be under the bond fide personal conduct and supervision of a duly qualified person," and for the "maintenance of a register of shops where poisons may be sold, and also a register of the duly qualified chemists conducting each such shop," and requires that "companies keeping open shops for the sale of poisons shall have that portion of their business managed by a duly qualified chemist as director."

The Army Medical Services.

The Secretary of State for War in his memorandum relating to the Army Estimates for 1907-08 makes a brief reference to medical matters in the army. He states that the principles of sanitation are being steadily inculcated in the army by means of a school of army sanitation at Aldershot for combatant officers and men, and for non-commissioned officers and men of the Royal Army Medical Corps.

by the compulsory examination of all officers in hygiene, the distribution of literature, and by the delivery of lectures by officers of the Royal Army Medical Corps. By these means, and by the institution of sections of specially trained men to look to the sanitary affairs of units in the field, it is confidently hoped to reduce the proportion of sick in future campaigns.

Public Health Legislation.

The Earl of ONSLOW has intimated that he intends to initiate a discussion in the House of Lords on various Public Health Acts. He intends to ask the Government whether, in its opinion, the time has arrived for the extension of these Acts. No date has yet been named for the discussion.

The Registration of Nurses.

Mr. CLAUDE HAY has given notice that he intends to introduce a Bill to provide for the better training and registration of nurses and for the voluntary registration of private nursing homes.

The Public Health Acts.

Mr. J. W. WILSON on Tuesday introduced a Bill to amend the Public Health Acts.

HOUSE OF COMMONS.

WEDNESDAY, FEB. 20TH.

Cerebro-spinal Meningitis.

Mr. LUPTON asked the President of the Local Government Board, with reference to the recent outbreaks of spotted fever in the United Kingdom, whether there was any practical method of ascertaining that a tube of vaccine virus was at the time of use free from the contagion of cerebro-spinal meningitis; and, if the answer be in the negative, whether he would discontinue the manufacture of calf lymph until it could be guaranteed free from all extraneous disease germs.

Mr. JOHN BURNS replied: I am advised that there is a practical method of ascertaining the presence of the organism of cerebro-spinal meningitis in vaccine lymph, and that in the periodic bacteriological examination which is made of each batch of calf lymph this organism if present and alive would be detected. I am further advised that the processes adopted in the elimination of extraneous micro-organisms from the lymph would undoubtedly destroy the organism in question.

Mr. J. W. WILSON: What steps are being taken to secure protection from the disease?

Mr. BURNS: I am issuing a circular to the sanitary authorities relative to this disease and am forwarding a memorandum to them on the subject that has been prepared by the medical officer to the Local Government Board. The report has been made by Dr. M. H. Gordon to me on the micrococcus of epidemic cerebro-spinal meningitis, with special reference to identification in the upper respiratory passages. That report is in the press and will be published in the course of a few days. If further medical investigation is found necessary on this matter I shall not hesitate to take prompt steps.

Mr. WILSON: Does the right honourable gentleman expect any immediate danger?

Mr. BURNS: I do not think there is any immediate cause for panic or alarm. The whole of the medical authorities are apprised of the position and are doing the best they can in the matter.

Mr. JOHN DILLON: Has the right honourable gentleman power to take or has he taken any means to control the trade in old clothes in the city of Glasgow? The disease seems to have spread in that centre and I should say that trade would be exceedingly dangerous.

Mr. BURNS: The Local Government Board is taking every step to ascertain what are the causes likely to spread this disease and will specially inquire into the question raised by the honourable Member.

Vaccination Fees.

Mr. RAPHAEL asked the President of the Local Government Board for what reason the Board had insisted that the Poor-law guardians of the borough of Derby should pay the medical officer of the union workhouse a fee of 2s. 6d. for each case of vaccination at the workhouse in excess of the inclusive salary he was ready and willing to accept from the guardians; and whether he would give instructions to his department that in the future no action should be taken to frustrate the endeavours of local authorities to secure economical administration.

Mr. BURNS replied: The law contemplates that a contract will be entered into with a workhouse medical officer in respect of the vaccination of the persons in the workhouse and that a fee will be paid him in respect of each such vaccination. The remuneration for this purpose cannot properly be included in his salary as the remuneration covers duties which would not devolve on him in the absence of a contract. But the fact that separate provision will be made in respect of fees for vaccination may of course be taken into account in determining the amount of the salary.

The Prosecution of Milk Vendors.

Mr. RENDALL asked the honourable Member for South Somerset: as representing the President of the Board of Agriculture, whether, having regard to circulars issued by the Board concerning milk which fell below the legal standard owing to the conduct of the cow and not owing to the corrupt act of the cow owner or the milk distributor, he proposed to introduce legislation to safeguard milk vendors from prosecution in cases where it was proved that milk had been sold in the condition in which it left the cow.—Sir EDWARD STRACHEY replied: The suggestions made by my honourable friend will receive careful consideration in the event of any further legislation as to the sale of milk being proposed. In the meantime we shall be happy to make inquiries in any case in which it appears that proceedings have been instituted with regard to the alleged adulteration of milk either under a misapprehension of the law or without due consideration of the facts of the particular case.

Mr. RENDALL asked the honourable Member for South Somerset: as representing the President of the Board of Agriculture, whether he would introduce legislation in regard to the sale of milk, to provide that where it was apparent to the inspector under the Sale of Food and Drugs Act that the producer was responsible for the adulteration, and

¹ The provisions of this measure are stated in an annotation (see p. 623).

will also bequeath £400 each to the National Hospital for Paralyzed and Epileptic, the Hospital for Incurables, Putney, Windsor Infirmary, Maidenhead Cottage Hospital, Earlswood Asylum for Idiots, and the Infant Orphan Asylum at Wanstead.

THE Leicester town council at its meeting on Tuesday last increased the salary of Dr. O. K. Millard, the medical officer of health of the borough, from £600 to £700 per annum.

SHANGHAI GERMAN MEDICAL SCHOOL.—Dr. Claude du Bois Reymond, a son of the eminent physiologist, who is now *privat-docent* of ophthalmology in Berlin, has been offered a post as teacher of ophthalmic surgery in the Shanghai German Medical School. The appointment is for six years.

WEST LONDON POST-GRADUATE COLLEGE.—The Post-Graduate College attached to the West London Hospital has now been recognised by the University of London as an institution where candidates for the M.D. degree can spend the necessary year of hospital study after passing the degree of M.B.

SCARCITY OF CERTIFIED MIDWIVES.—At a meeting of the Loughborough (Leicestershire) rural district council on Tuesday, Feb. 19th, the medical officer of health of the county wrote drawing attention to the scarcity of certified midwives in the district. He asked the council to inform him if it knew of any suitable women who would be likely to take up the work.

PRIZE FOR INDUSTRIAL HYGIENE.—The council of the Society of Arts is prepared to award, under the terms of the Benjamin Shaw Trust, a gold medal, or a prize of £20, "for any discovery, invention, or newly-devised method for obviating or materially diminishing any risk to life, limb, or health incidental to any industrial occupation, and not previously capable of being so obviated or diminished by any known and practically available means." Descriptions of inventions must be sent in not later than Dec. 31st, 1907, to the secretary of the Society of Arts, Adelphi, London, W.C., either under the inventor's name or under a motto, accompanied by a sealed envelope inclosing the name. The judges will be appointed by the council. The council reserves the right of withholding the prize or of awarding a smaller prize or smaller prizes.

BRITISH MEDICAL BENEVOLENT FUND.—The annual general meeting of the supporters of this fund was held at 15, Wimpole-street, W., on Feb. 19th. Sir William H. Broadbent, the President, was unable to be present, and Sir William S. Church being prevented by a meeting of the amalgamated societies from presiding as announced, the chair was taken by Mr. E. Parker Young, chairman of the committee. The report of the committee for the preceding year was read and adopted, and was ordered to be printed for circulation. In the annuity department the income was £2485 2s. The following legacies were received and duly invested: Dr. Grieve, £259 10s. 6d.; Dr. W. Burns, £90; Dr. Parsons, £100; Dr. Cameron, £100; and Dr. Trollope, £500; total, £1049 10s. 6d. In the grant department the amount distributed was £1619 5s., as against £1562 in the preceding year. The total amount of money received, however, appeared to be less by £150. In 1905 a special appeal was made which brought in donations to the amount of £841. During the year without any special appeal the donations reached the satisfactory sum of £226, while the annual subscriptions showed the remarkable increase of £251. This increase, though the result in part of personal effort, was largely due to the generous assistance rendered by the editors of THE LANCET and of the *British Medical Journal* in permitting the publication in their columns each month of the proceedings of the committee with an abstract of the cases relieved. This simple record of facts told in an eloquent and touching way the work and wants of the fund. A special donation of £20 was again received from Miss Flower to enable some of the most deserving cases to get a summer holiday. Other special donations to provide special Christmas gifts were received from Miss Flower of £20, from Dr. Satchell of £10 10s., and other sums from Mr. Patmore Sheehy and Miss Breeze. The accounts were audited as usual by Messrs. Deloitte, Plender, Griffiths, and Co., chartered accountants. The committee, while glad

that the favourable anticipations made in the report of last year had been realised, felt only too well how much still remained to be done before the fund was recognised as widely and supported as liberally as it deserved and ought to be, and called upon all interested in its work to continue, and, if possible, to increase, their efforts on its behalf.

THE MIDDLESEX HOSPITAL.—A meeting of the court of governors was held on Feb. 28th, when Mr. Henry Morris occupied the chair. After the transaction of the usual business an address was presented to Nurse Sarah Cross in recognition of her heroic services during the recent earthquake in Jamaica.

GUY'S HOSPITAL.—The treasurer of Guy's Hospital has received a bequest of £1000 under the will of the late Mr. Charles James Oldham, F.R.C.S. Eng., of Brighton for the purpose of endowing an annual prize in ophthalmology at the Medical School. A further anonymous donation of £200 has also been received for the fund for the Endowment of Medical Education and Research.

ROYAL PORTSMOUTH HOSPITAL.—Two important meetings in connexion with the Royal Portsmouth Hospital were held last week. On Feb. 22nd the mayor presided over a meeting at the town hall, which was held to inaugurate a fund for the erection of new children's wards in place of the present inadequate, ill-adapted, and insanitary ones. A generous contribution of £500 was made by Mr. J. J. Young, J.P. (chairman of the committee of management), and a sum of £2525 was obtained before the meeting closed. On the following day the annual meeting of the subscribers was held, Mr. T. A. Bramson, M.P., presiding. The report, which was a satisfactory one, stated that there was only a small deficit of £89 on the year's working, there was an increase of 1280 cases in the number of patients treated, and the average cost per bed occupied on total ordinary expenditure was £58 11s. Only two hospitals in the kingdom were conducted on more economical lines. The Hospital Saturday Fund contributed £973, and £804 11s. were received from the Hospital Sunday Fund.

MRS. CRAIGIE MEMORIAL FUND.—A committee, which has been formed by some of the friends of the late Mrs. Craigie (John Oliver Hobbes) to raise subscriptions for a memorial to her, appeals to the medical profession on the ground that the deceased novelist was formerly a student at University College. It is proposed that, in the event of sufficient funds being collected the memorial should include the following: (1) a portrait plaque, in marble or bronze, to be placed in University College, London; (2) a replica of the plaque to be placed in a suitable position in the United States; (3) a scholarship for the study of modern English literature to be given annually in England; and (4) a similar scholarship to be given annually in the United States. Subscriptions may be sent to one of the honorary treasurers—viz., the Hon. Mrs. Rochfort Maguire, 3, Cleveland-square, St. James's, S.W.; Mrs. George Cornwallis West, Salisbury Hall, St. Albans; Miss Blanche Eliot, 8, Onslow-gardens, South Kensington, S.W.; or to Messrs. Barclay and Co., Limited, 1, Pall Mall East, London, S.W.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Public Health Bill.

THE text of the Public Health (Regulations as to Food) Bill which was brought in by Mr. JOHN BURNS on the second day of the parliamentary session has been published. It provides that the power of making regulations under the various Public Health Acts shall include "the power of making regulations authorising measures to be taken for the prevention of danger arising to public health from the importation, preparation, storage, and distribution of articles of food or drink (other than drugs or water) intended for human consumption." The Bill further sets forth that without prejudice to the generality of the powers so conferred, those regulations may (a) provide for the examination and taking of samples of any such articles; (b) apply, as respects any matters to be dealt with by the regulations, to any provision in any Act of Parliament dealing with the like matters, with the necessary modifications and adaptations; and (c) provide for the recovery of any charges to be made by the regulations. Both Mr.

WEDNESDAY, FEB. 27TH.

Guardians and Cerebro-spinal Fever.

Mr. ALDEN asked the President of the Local Government Board whether he would issue to boards of guardians, relieving officers, and poor-law medical officers the circular as to spotted fever or cerebro-spinal meningitis which he proposed to issue to the sanitary authorities; and further, whether he would suggest to the guardians and relieving officers that poor sick persons and the poor parents of sick children should not at the present time, if they stated that they were unable to pay for a doctor, be deterred from making application for medical assistance by the fear of having the relief made a debt or by the fear of having to come before the guardians or a committee.—**Dr. JOHN BURNS** replied: I am sending to boards of guardians the memorandum which accompanied the circular referred to with a view to its distribution amongst poor-law medical officers. As regards the latter part of the question, I have no reason to suppose that persons properly entitled to receive medical relief are deterred from applying or it by the considerations mentioned by my honourable friend and it does not seem to me necessary to communicate with the guardians on the subject.

BOOKS, ETC., RECEIVED.

Dunnett's Hospital and Charities. 1907. By Sir Henry Dunnett, K.C.B. Price 7s. 6d. net.

the distributor had taken the precaution provided for by the Act, the distributor's business should not be damaged by having his name dragged before the public through the medium of the police court.—Mr. JOHN BURNS (President of the Local Government Board) replied to the question. He said: I will note the suggestion in the question for consideration in connexion with any legislation for the amendment of the Sale of Food and Drugs Act; but at present it appears to me that there would be difficulties in adopting the proposal.

Mr. ALDEN: May I ask the right honourable gentleman whether he regards the Act as a protection to the consumer or to the trader?

Mr. BURNS: The object of the Act is primarily to protect the consumer and we ought to try to get both at the distributor and the producer. Under the present law the distributor alone is liable. I hope some day both will be liable.

Vaccination in Scotland.

Mr. McOALLUM asked the Secretary for Scotland, if the law is to be altered in England regarding compulsory vaccination, on the plea that the impediments placed in the way of conscientious objections were unsatisfactory, when it might be expected that similar advantages would be extended to Scotland.—Mr. SINCLAIR: I have undertaken to consider this question but I am unable at present to give any definite reply to it.

THURSDAY, FEB. 21ST.

The Health of Belfast.

Mr. MCKILLOP asked the Chief Secretary to the Lord Lieutenant of Ireland whether he was aware that a commission was being appointed to inquire into the high death-rate in Belfast and the sanitary regulations in that city; that the names already published did not include any unofficial member of the medical profession; and whether, in view of the importance of the question, he would consider the advisability of appointing to the commission some such representative acquainted with the laws of sanitation in Ireland.—Mr. BIRRELL replied: I understand that my predecessor gave the most careful consideration to the constitution of the departmental committee which has been appointed to inquire into the sanitary condition of Belfast and there appears to be no sufficient reason for adding to the number. In addition to the expert knowledge possessed by the official medical members who have been appointed, the committee will doubtless have the advantage of hearing the views of a number of eminent members of the medical profession who are fully acquainted with the sanitary condition of Belfast and with the laws of sanitation generally.

Medical Inspection in Scotch Schools.

Mr. GULLAND asked the Secretary for Scotland whether his proposed Education Bill for Scotland would include the provision of meals for school children; and whether he would consider the granting of powers for medical inspection and for the establishment of play centres, more stringent regulations for enforcing compulsory attendance, and the extension of the definition of cruelty, so that parents might be prosecuted who allowed their children to be insufficiently clothed or verminous.—Mr. SINCLAIR said in reply: Provision of meals will be included. The various other matters mentioned by my honourable friend are under consideration, but it is not possible as yet to give any further information in regard to the contents of the Bill.

Soldiers and Tuberculosis.

Major SEELY asked the Secretary of State for War how many men were discharged from the army during the past year suffering from tubercle of the lung; how many of these men were sent to their homes, with a notification to the local medical officer of health; and how many were sent directly to hospital or sanatoriums, stating the particular hospitals or sanatoriums and the numbers sent to each.—Mr. HALDANE answered: The statistics available at the War Office do not contain the required information. It will be necessary to call for returns from all army hospitals at home. When the information has been collected I will have it forwarded to my honourable and gallant friend.

The Royal Commission on Tuberculosis.

Answering Mr. O'GRADY, Mr. RUNCIMAN (Secretary to the Treasury) said: The expenditure on the Royal Commission on Tuberculosis out of the vote for Temporary Commissions up to Jan. 31st, 1907, has been £46,193. I understand that liabilities have also been incurred to the amount of £2700 for stationery and printing.

Pellagra in Egypt.

Mr. JOHN ROBERTSON asked the Secretary of State for Foreign Affairs whether, in view of the prevalence in Egypt of the disease pellagra, resulting from the ingestion of bad maize, he would advise the Egyptian Government to take some such measures of prevention as had been prescribed by the Italian law against pellagra of July 21st, 1902.—Sir EDWARD GREY said: I have no information on the subject but will make inquiries.

MONDAY, FEB. 25TH.

Cerebro-spinal Fever.

Sir HOWARD VINCENT asked the President of the Local Government Board whether, having regard to the recent importation of that dangerous alien disease known as spotted fever, and the rapidity with which it spread, he would issue strict instructions for the inspection of all alien immigrant ships, and, following the precedent of 1892 at the time of the outbreak of cholera at Hamburg, direct that no suspected case should be allowed to land under any pretext.—Mr. JOHN BURNS answered: Cerebro-spinal fever is not necessarily a disease imported from abroad, and at the present time I am not aware that there is any exceptional prevalence of it on the Continent. The circumstances in relation to this disease are different from those affecting an outbreak of cholera such as that referred to in the question. As regards alien immigrants on immigrant ships which come within the Aliens Act, 1905, the hon. Member is aware that they are inspected under the Act, and that the Act requires that leave to land shall be withheld in the case of any such alien if, owing to disease, he appears likely to become a detriment to the public.

Meat Inspection in Scotland.

Mr. WATT asked the President of the Local Government Board whether in view of the dissatisfaction as to the unequal manner in which the officials of local authorities in Scotland carried out their inspection of meat he would appoint a veterinary surgeon, with practical experience of the work, to report on the standard and system

of inspection in operation in the different districts.—Mr. SINCLAIR answered: An inquiry into the methods of meat inspection by office of local authorities in Scotland is now going on.

Infantile Mortality.

Mr. ROGERS asked the President of the Local Government Board whether he intended to introduce any legislation this session dealing with the abnormally high death-rate of children under five years of age; and what steps were being taken to direct the attention of local authorities to this matter.—Mr. BURNS said, in reply: I am giving attention to this subject and I hope that it will be practicable during the present session to introduce legislation bearing upon it. I am impressing on local authorities and their officers by circulars and otherwise the importance of collecting data and studying the problem connected with it.

The Royal Commission on Tuberculosis.

Mr. ALDEN asked the President of the Local Government Board whether he opposed to take in carrying out the conclusions of the Royal Commission on Tuberculosis, seeing that not only the Commissioners but a large number of experts outside the Commission were agreed that more stringent measures were required than those at present enforced to prevent the sale of such milk as contained tubercle bacilli.—Mr. JOHN BURNS replied: I am giving attention to the report of the Royal Commission but am not at present in a position to take action upon it. The report has only recently been presented and as yet the appendices referred to in it have not been issued. The conclusions of the Commissioners relate to matters of much importance and must be carefully considered both by the Local Government Board and the Board of Agriculture.

The Army Medical Department.

Mr. HALDANE, in the course of his statement on the Army Estimates, said that the deficit of men in the Army Medical Department was very serious indeed. They required 8500 men to look after the hospitals, but they had only 4700, and 2000 reservists, so that the deficit was 1800. That would be a bad thing for successful mobilisation and they would try to draw from civilian sources. He did not forget that on mobilisation they required nurses to go to the hospitals. Various schemes were under consideration and he could not speak with confidence yet. The whole topic of nurses was one which he approached with diffidence as it was one of the most difficult with which he had to deal. Further on in his speech the Secretary for War said that in the case of the army medical element they had to have a special bridge between the first and the second lines of defence, and the special contingent that they wanted for the field force was some 331 medical officers, 30 quartermasters, and 4400 men, which would provide for wastage and give them enough to make up the deficiency which they required for mobilisation of the first line. They proposed to organise—and the negotiations for this were in progress—a large territorial Army Medical Corps analogous to the Regular Army Medical Corps. The British Medical Association had already taken a great interest in the matter and had suggested that the War Office should organise this corps not merely locally but as a great corps—just as the Engineers and the Artillery were great corps—organised under the Director-General of the Army Service Corps. His department had accepted that suggestion and were going to organise one great Army Medical Corps, and they hoped in that way to get a very large number of people connected with the medical profession to take an interest in the army medical branch of the service, both regular and second line. In that fashion they hoped to get both officers and men who would go out on mobilisation. He might say that his department entertained no doubt that they should be able to succeed to some extent in that and, they thought, to the full extent of their desires.

TUESDAY, FEB. 26TH.

X Ray Tubes.

In answer to Mr. WEIR, Mr. HALDANE said: The x ray tubes required for military hospitals are purchased from contractors in this country who obtain many of their supplies from continental manufacturers.

The Dismissal of Poor-law Medical Officers in Scotland.

Mr. OATHART WATSON asked the Secretary for Scotland whether he was aware of the dismissal from office of Dr. George Duncan, the Poor-law medical officer of the parishes of Kintail, Glenelish, and Lochalsh after 50 years of public service; would he say if he failed or neglected or refused to perform the duties of his office, or if he was found unfit or incompetent to discharge them; had the Local Government Board made any inquiry into the case; and, if so, what reasons had been alleged by the parish councils for his dismissal.—Mr. SINCLAIR replied: I have to reply to the first part of the question in the affirmative, but, as the honourable Member is aware, the Board has no power to interfere in the matter of dismissal of a parochial medical officer. Dr. Duncan, who is the medical officer of the three very large parishes named, is of advanced years, and I understand that as he has failed to implement an agreement made with him three years ago to appoint an assistant he has been asked to resign as from July 1st next. I am not aware that unfitness or incompetency of any kind has been alleged.

A Case of Phosphoric Necrosis.

Sir CHARLES DILKE asked the Secretary of State for the Home Department whether his attention had been called to the fact that a further death from necrosis in the match trade was reported for January of this year; and whether, in view of the international interest taken in the question of phosphorus poisoning, he would issue to the House full details of this case as was done by the then Secretary of State with regard to the cases occurring in 1905.—Mr. GLAUCOWSKI (in a written answer) replied: Yes, Sir. When I heard of this (in a regrettable occurrence I at once directed a visit to be paid to the factory by the Chief Inspector of Factories and Mr. Cunningham, one of my Assistant Under Secretaries of State. They have made a report to me which I shall lay upon the table of the House, but I may say that they discovered no breach of the rules. The case was a very exceptional one, the deceased being a man with one leg who had to work in a sitting posture and had also an inveterate habit of chewing tobacco. For both these reasons he was exposed to danger which his fellow workers escaped. He had, moreover, worked in yellow phosphorus for years before special rules were established, and had, it is known, long had the seeds of necrosis in his system. I shall propose an amendment of the special rules to prohibit the chewing of tobacco.

Notes, Short Comments, and Answers to Correspondents.

A RETIRED MEDICAL MAN AND GOOD OPENINGS.

In the issue of THE LANCET of Feb. 23rd the following advertisement was published:—

Wanted, by Medical Man with some private means but limited capital, a small PRACTICE or NUCLEUS, with good scope for increase. Preferably unopposed and in Country district, South of England for choice. Moderate sized house, with grounds, &c., necessary. Premium must be small.—Address, No. 235, THE LANCET Office, 423, Strand, W.C.

One of the replies to the advertisement has been forwarded to us by the advertiser and we think merits publication, as it comes from a medical man but shows a remarkable ignorance of the rules that should govern the mutual conduct of members of a profession:—

6, Stone St. Faversham, Kent, Feb. 24, 07.

In replying mention No. 235, LANCET.

DEAR SIR.—An excellent opportunity occurs about 23 miles from London (South) where there is a population of over 7000 with one unpopular medical man. There is no doubt a good practice to be made in a short time by an energetic cyclist. A wealthy resident has two good houses empty with grounds to let at £25 and £55. He is desirous of getting another doctor there for himself and his tenants, as well as, for others who are not satisfied with the present man. There is a third good house to let in a prominent situation at £43. Three reception-rooms, six bedrooms and garden, coach-house and stables can be had, Gravel soil, lovely country, High ground. Large works are about to be begun in this place employing thousands of hands, so that now is the time for anyone to start. This scheme will increase the population to a great extent, bringing large numbers of all classes and improve the place beyond recognition. I can insure the support of any good man by my wealthy friend, the Rector and other friends I have there.

I am asking a small premium to be agreed upon at an interview. I should say that 5 hundred or more would be done the first year; but the possibilities of the place as a field for medical work are very good.

I am, yrs. faithfully,

F. F. JAY, M.D.

I am a retired doctor, and have been asked to find a man to take this fine chance up.

This is not the first time that it has been brought to our notice that Dr. Jay replies to advertisements in THE LANCET with offers to introduce the advertiser to remunerative practices in return for a premium. We recommend our advertisers not to reply to Dr. Jay. The medical agents are much more likely to be able to introduce advertisers to the opening which they require than any medical man, retired or otherwise, can possibly be. A medical man may know of a good opening in his immediate neighbourhood, but we do not admire the frame of mind which tempts him to try to obtain a small premium for the information. All such openings must be at the expense of some medical colleagues already resident in the neighbourhood.

THE ARGEMONO MEXICANA.

To the Editors of THE LANCET.

SIR.—In reply to "Enquirer" in THE LANCET of Feb. 16th, p. 477, the plant to which he refers, *Argemone Mexicana*, was formerly considered to contain morphine, but this alkaloid has been proved to be absent by J. O. Schlatterbeck (Journal of the American Chemical Society, Vol. XXIV, p. 238). The plant contains the alkaloids berberine and scopoline, of which the latter is identical with the base erroneously called argemone by Peckolt. Schlatterbeck found a considerable quantity of potassium nitrate among the inorganic salts present in the plant. As the drug has attracted some little attention in the United States there should be no difficulty in obtaining preparations of it by entering the name of a wholesale druggist.

I am, Sir, yours faithfully,

HISMAUS.

TORQUE.

To the Editors of THE LANCET.

SIR.—In reading the last paragraph under the heading of "Looking Back" in THE LANCET of Feb. 23rd I was puzzled as to the meaning of the word "torque" and could not find it in any dictionary at my disposal. Then it dawned on me that the word was probably "torque," meaning a twisted metal collar worn around the neck by the ancient Gauls and British chiefs and apparently originating with the Persians. It was made of gold or bronze and the ends of the broken circle usually terminated in ornamental knobs or in turned back hooks for interlocking. I have learnt that in B.C. 351 Titus Manlius Imperator Torquatus wore one which was a personal trophy, hence the name in Falstaff's "Terms in Art." There are also several in the gold ornaments room at the British Museum. Some are in the Sir A. W. Franks's collection and others are in the Morel collection. One gold torque is variant spelling adopted by the British Museum. One gold torque is said to have been found at a depth of eight feet. Another large

gold one was found in 1856 at Ashill, near Watton, in Norfolk, and a reference is given to Norfolk Archaeology, Vol. V., p. 193. Others were found at Boyton in Suffolk one in Lincolnshire, four near Elgin in Scotland, one at Ballinacree, near Boyle, co. Roscommon, and a large one at Castlepoint, Dover, presented by Mr. Robert Chignell in 1881. Several bronze ones were obtained from Gaulish cemeteries in the department of the Marne, France. It appears that they often formed a great part of the wealth of the wearer. I see that the Welsh call it "torch" and "Gorthorch." If "torque" was the word meant, this note may perhaps interest some of your readers.

I am, Sir, yours faithfully,

London, Feb. 25th, 1907.

X. Y. Z.

HUDIBRASTIC LANGUAGE.

A CORRESPONDENT has asked us the meaning that it was intended to convey when using the expression "Hudibrastic vocabulary" in a leading article last week. The language of Hudibras, as described by his immortal creator, is almost precisely that of certain modern text-books, the contents of which are often worthy of better exposition. The more grotesquely involved the language of such books is, the more closely is it humbly followed by certain modern advertisements. The following is Butler's description of his hero's language:—

"His speech,

In loftiness of sound, was rich
A Babylonish dialect,
Which learned pedants much affect;
It was a party-colour'd dress
Of patch'd and piebald languages;
'Twas English cut on Greek and Latin,
Like fustian heretofore on satin;
It had an odd promiscuous tone,
As if he had talk'd three parts in one.
Which made some think, when he did gabble,
He had heard three labourers of Babel,
Or Cerberus himself pronounce
A leash of languages at once."

THE COMPOSITION OF BOOT BLACKING.

To the Editors of THE LANCET.

SIR.—Having seen a paragraph in your issue of Feb. 16th referring to the alleged evil effects of sundry boot-blackings, we, as one of the very oldest firms of blacking manufacturers, write to bring to your notice the following facts. At the exhibition of 1882 we were awarded the only gold medal for blacking; before the award was made our Meltonian blacking was subjected to the most severe analysis and it was proved that there was absolutely nothing of an injurious nature in it, but that, on the contrary, all the ingredients tended to soften and preserve the leather. Our endeavour has always been to keep our preparations up to this very high standard; that our endeavour has been successful is shown by their unique reputation, not only in this country but all over the civilised world. Our reason for writing is that we feel, as no doubt other high-class manufacturers will feel also, that a charge has been brought against the whole trade that is absolutely false in the case of those makers who have a reputation to lose.

We are, Sir, yours faithfully,

E. BROWN AND SONS,
Manufacturers of Meltonian blacking and other boot
preparations.

7, Garrick-street, W.C., Feb. 25th, 1907.

THE NATIONAL REGISTRATION OF PLUMBERS.

THE clerk to the Worshipful Company of Plumbers has forwarded to us a facsimile of the portable registration ticket for the year 1907 which is granted by the company to a registered plumber. The ticket contains spaces for the name and address of the registered plumber and for his signature, while the date of the year for which the certificate is valid is printed in large type across the face. The colour of the date will vary each year and for the current year it is of a purplish-pink colour. Complaints, if any such exist, of work done by registered plumbers should be addressed to the Worshipful Company of Plumbers in order that the company may deal with the matter in the public interest. Plumbing is, of course, so important a trade as regards sanitation that it is necessary for the health of the public that its members should have some means of distinguishing between the competent and the incompetent as it is in the case of those to whom they intrust the care of their bodies, and we are therefore glad to congratulate the Plumbers' Company upon the steps which it has taken with a view to secure this desirable result.

THE FINGER-STALL TEST.

THE finger-stall test is designed to avoid certain deformities of the mouth which Dr. T. P. Pedley maintains are caused by the sucking of ordinary rubber teats and "baby comforters." Dr. Pedley attributes to the unnatural pressure of most of the teats in use upon the baby's jaws certain deformities of the roof of the mouth and the interior of the nose which are subsequently followed, he says, by obstructions to breathing through the nose. When the shape and pliability of the test are that of a good-sized rubber finger-stall the infant requires to make little effort in order to attract the milk. The finger-stall test is supplied by Messrs. Lynch and Co., Limited, of Silver-street, Falmouth, London, E.C.

SHERBATT AND HUGHES, 60, Chandos-street, London, W.C.

The Journal of Obstetrics and Gynaecology of the British Empire. Editor: Charles J. Cullingworth, M.D. Assistant Editor: John S. Fairbairn, M.B. Volume X. July to December, 1906. Price 12s. 6d. net.

WILSON, EFFINGHAM, 54, Threadneedle-street, London, E.C.

The Cornish Tin Mining Manual. By H. A. H. Russell. Price 1s.

YEAR BOOK PUBLISHERS, Chicago. (G. GILLIES & CO., 23, Gibson-street, Hillhead, Glasgow.)

The Practical Medicine Series. Under the General Editorial Charge of Gustavus P. Head, M.D. Volume X. Skin and Venereal Diseases, Nervous and Mental Diseases. Edited by W. L. Baum, M.D., Hugh T. Patrick, M.D., William Healy, A.B., M.D. Price 5s.

Appointments.

Successful applicants for Vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.

DOBIE, W. HENRY, M.B., C.M. Edin., M.R.C.S., has been appointed Honorary Surgeon to the Chester Infirmary.
GLEGG, R. ASHLEIGH, M.D., Ch.B. Edin., D.P.H., has been appointed Assistant Medical Officer of Health of the County of Ayr.
GOULD, HAROLD UTTERTON, M.A., M.B., B.C. Cantab., L.R.C.P. Lond., M.R.C.S., has been appointed District Medical Officer by the Shaftesbury (Dorset) Board of Guardians.
GREFF, T. A., M.D., F.R.C.S. Edin., has been appointed Surgeon in Charge of the Nose, Throat, and Ear Department at the Bristol Royal Hospital for Sick Children and Women.
GROVES, B. J. C., M.B., Ch.B. Edin., has been appointed House Surgeon at the Brighton, Hove, and Preston Dispensary.
HAMIL, THOMAS FRANCIS, L.R.C.P., L.R.C.S., L.M. Edin., has been appointed Medical Officer of Health for the Shaftesbury (Dorset) Rural District.
HARTIGAN, T. J. P., F.R.C.S. Eng., has been appointed Dermatologist to the Alexandra Hospital, Queen-square, W.C.
JOHNSTONE, G. A., M.B., Ch.B. Aberd., has been appointed House Surgeon at the Bangor Infirmary.
MACPHEAL, DUGALD H. M.B., Ch.B. Glasg., has been appointed Extra Physician to the Glasgow Central Dispensary.
MAY, W. NORMAN, M.B., B.S. Lond., has been appointed Resident Medical Officer at the East London Hospital for Children and Dispensary for Women.
SEWELL, D. LINDLEY, M.B., B.S. Lond., M.R.C.S., L.R.C.P. Lond., has been appointed Honorary Assistant Surgeon to the Manchester Ear Hospital.
WILLIAMS, LIONEL HENRY, M.D. Durh., M.R.C.S., L.S.A., has been appointed Deputy Medical Officer for the Thornbury (Gloucestershire) District and Workhouse.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement (see Index).

ABERDEEN UNIVERSITY.—McRobert Fellowship for Cancer Research. Salary £200 to £250.
ASTON-UNDER-LYKE DISTRICT INFIRMARY AND CHILDREN'S HOSPITAL.—House Surgeon. Salary £120 per annum and fees. Also Junior House Surgeon for six months. Salary at rate of £50 per annum. Board, rooms, washing, &c., in each case.
BIGGLESWADE RURAL DISTRICT COUNCIL.—Medical Officer of Health. Salary £100 per annum.
BIGGLESWADE URBAN DISTRICT COUNCIL.—Medical Officer of Health. Salary £25 per annum.
BIRKENHEAD AND VIRAL CHILDREN'S HOSPITAL, Woodchurch-road, Birkenhead.—House Surgeon. Salary £100, with board, residence, and laundry.
BIRKENHEAD UNION INFIRMARY, WORKHOUSE, AND SANATORIUM.—Resident Assistant Medical Officer. Salary £120 per annum, with board, washing, and apartments.
BIRMINGHAM WORKHOUSE INFIRMARY.—Assistant Resident Surgical Officer. Salary £104 per annum, with apartments, rations, &c.
BODMIN, CORNWALL COUNTY ASYLUM.—Third Assistant Medical Officer, unmarried. Salary £140 a year, rising to £160, with rooms, rations, laundry, and attendance.

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 P.M.: Operations. Out-patient Demonstrations.—10 A.M.: Surgical and Medical. 11 A.M.: Eye.

EDITORIAL NOTICES.

It is most important that communications relating to the Editorial business of THE LANCET should be addressed exclusively "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office.

Lectures, original articles, and reports should be written on one side of the paper only, and WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WRITTEN ON THE BLOCKS TO FACILITATE IDENTIFICATION.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners. Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale and advertising departments of THE LANCET should be addressed "To the Manager."

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

THE INDEX TO THE LANCET.

The Index and Title-page to Vol. II. of 1906, which was completed with the issue of Dec. 29th, were given in

VOLUMES AND CASES.

VOLUMES for the second half of the year 1906 are now ready. Bound in cloth, gilt lettered, price 18s., carriage extra.

Cases for binding the half year's numbers are also ready. Cloth, gilt lettered, price 2s., by post 2s. 3d.

To be obtained on application to the Manager, accompanied by remittance.

TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and not to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will insure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

THE COLONIAL AND FOREIGN EDITION (printed on thin paper) is published in time to catch the weekly Friday mails to all parts of the world.

The rates of subscriptions, post free, either from THE LANCET Offices or from Agents, are:—

FOR THE UNITED KINGDOM.		TO THE COLONIES AND ABROAD.	
One Year	£1 12 6	One Year	£1 14 8
Six Months	0 16 3	Six Months	0 17 4
Three Months	0 8 2	Three Months	0 8 8

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Offices, 423, Strand, London, W.C.

TO COLONIAL AND FOREIGN SUBSCRIBERS.

SUBSCRIBERS ABROAD ARE PARTICULARLY REQUESTED TO NOTE THE RATES OF SUBSCRIPTIONS GIVEN ABOVE. It has come to the knowledge of the Manager that in some cases higher rates are being charged, on the plea that the heavy weight of THE LANCET necessitates additional postage above the ordinary rate allowed for in the terms of subscriptions. Any demand for increased rates, on this or on any other ground, should be resisted. The Proprietors of THE LANCET have for many years paid, and continue to pay, the whole of the heavy cost of postage on overweight foreign issues; and Agents are authorised to collect, and generally do so collect, from the Proprietors the cost of such extra postage.

The Manager will be pleased to forward copies direct from the Offices to places abroad at the above rates, whatever be the weight of any of the copies so supplied. Address—THE MANAGER, THE LANCET OFFICES, 423, STRAND, LONDON, ENGLAND.

METEOROLOGICAL READINGS.

(Taken daily at 8.50 a.m. by Stewart's Instruments.)

THE LANCET OFFICE, Feb. 25th, 1907.

During the week marked copies of the following newspapers have been received:—Evening Telegraph (Toronto), Shipley Times, North Express, Weekly Times and Telegraph, Fort-wear, Nottingham Daily Express, Boylay Gazette, The Baker and Confectioner, Newcastle Chronicle, Bristol Times, Manchester Courier, Standard, Yorkshire Telegraph, Tribune, Daily Chronicle, Telegraph, Morning Post, Morning Leader, Liverpool Post, Sheffield Telegraph, Coroner's Herald, Local Government Journal, Carlisle Express, &c.

DEFECTIVE CHILDREN.

To the Editors of THE LANCET.

SIRS,—In reply to "Quaerens" in THE LANCET of Feb. 16th, p. 478, and to another correspondent in your last issue, may I mention in this regard Shuttleworth's "Mentally Deficient Children: their Treatment and Training" (Lewis, Gower-street, W.O.). The second edition contains chapters on Provision for Special Classes under the Act of 1889.

I am, Sirs, yours faithfully,

RESPONDENTS.

Feb. 20th, 1907.

Diplomate.—Information with reference to the Brussels M.D. will be found in the Students' Number of THE LANCET, Sept. 1st, 1906, p. 564. The degree is registrable in this country if obtained prior to 1886. The secretary of the Brussels Graduates' Association is Dr. F. H. Edwards, whose address is Camberwell House, Peckham-road, London, S.E. Dr. A. R. Henchley, of 1, London-road, Canterbury, publishes a pamphlet containing notes on the Brussels M.D. examination and examples of the questions set.

F. J.—There is no reason why the parties should not marry supposing that such portion of the family history as is common to both is good. In the other event they should not marry, as the risk of perpetuating any taint would be considerable.

H. C. G.—We do not think our contributor's amusing note can be regarded as a serious contribution to surgery.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

Medical Diary for the ensuing Week.

OPERATIONS.

METROPOLITAN HOSPITALS.

MONDAY (4th).—London (2 P.M.), St. Bartholomew's (1.30 P.M.), St. Thomas's (3.30 P.M.), St. George's (2 P.M.), St. Mary's (2.30 P.M.), Middlesex (1.30 P.M.), Westminster (2 P.M.), Chelsea (2 P.M.), Samaritan (Gynaecological, by Physicians, 2 P.M.), Soho-square (2 P.M.), City Orthopaedic (4 P.M.), Gt. Out-patient Demonstrations.—10 A.M.: Surgical and Medical. 11 A.M.: Eye. HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST (Brompton).—4 P.M.: Lecture.—Dr. Hartley: Bronchiectasis.

ABSTRACT OF

The Goulstonian Lectures

ON

CERTAIN ACUTE INFECTIVE OR TOXIC
CONDITIONS OF THE NERVOUS
SYSTEM.

Delivered before the Royal College of Physicians of London

By E. FARQUHAR BUZZARD, M.D. OXON.,
F.R.C.P. LOND.,

ASSISTANT PHYSICIAN TO THE NATIONAL HOSPITAL FOR THE PARALYSED
AND EPILEPTIC, QUEEN-SQUARE, TO THE ROYAL FREE HOSPITAL,
AND TO THE BELGRAVE HOSPITAL FOR CHILDREN.

LECTURE I.

Delivered on March 5th.

MR. PRESIDENT AND GENTLEMEN,—If it were not a duty based upon tradition it would still be a spontaneous wish of my own that the opening words of these lectures should frankly express my appreciation of the honour which you have paid me in placing them in my hands. An honour in itself, it gains enhancement from a reference to the many distinguished names of those who have in the past filled, and worthily filled, the position in which I find myself to-day. A sense of diffidence must necessarily be one's lot in such circumstances, but encouragement and stimulation may be derived from the reflection that few, if any, of my predecessors have failed to justify their early distinction by their later work. An apology is owing for the somewhat vague title I have given to my subject and this can be best offered in the shape of a short explanation. There has never been in my mind any idea of embracing within these lectures the discussion of all the numerous and interesting questions concerning acute infective or toxic conditions of the nervous system. On the contrary, it has been my desire to confine my attention to a comparatively small group of diseases and to a few important points which arise in connexion with them.

The leading characteristic of the group which I have chosen is easily expressed in two words—acute paralysis; to be more precise, I wish to deal with the class of case in which a rapidly developed motor paralysis, involving the whole, or nearly the whole, of the voluntary musculature, is the important and conspicuous feature. To be included in this category a case must be acute, requiring only a few hours or a few days for its development, and it must present good grounds for the belief that it is of infective or toxic origin, certainty in this regard being often impossible in the incomplete state of our bacteriological knowledge. If we search for cases answering to this description we shall find them classified under the following titles: (1) acute anterior poliomyelitis; (2) Landry's paralysis; (3) acute toxic polyneuritis; and (4) acute ascending or diffuse or disseminated myelitis. Some of these titles have synonymous alternatives, and some, as we shall see later, are open to objection; but they are familiar terms, conveying some meaning to most of us, and will suffice for the purpose of rough classification. Doubtless you will agree that the differential diagnosis between these four conditions may in any particular patient form one of the most difficult of bedside problems, and that the questions of their exact pathological basis, of their pathogenesis, of their relation to one another and to other morbid conditions, of their specificity or non-specificity are all worthy of detailed debate, even if they are not all ripe for successful settlement. The only excuse I can offer for attempting this task is that I have had the opportunity of observing clinically and examining anatomically a considerable number of cases which fall within this category.

The opportunities for clinical observation and accession to notes I owe in many instances to the generosity of my colleagues at the National Hospital for the Paralyzed and Epileptic and the Royal Free Hospital, to whom I desire to acknowledge my gratitude. For ready help and advice in the preparation of specimens I am deeply indebted to Dr. Gordon M. Holmes and Dr. T. Grainger Stewart of the former hospital, Dr. Helen Chambers and Dr. Evelyn Woodward

No. 4353.

have also spared no trouble in providing me with material from the pathological laboratory of the Royal Free Hospital for a special investigation.

For the better understanding of what is to follow and for the purpose of avoiding the unnecessary repetition of elaborate descriptions I shall employ the time at my disposal to day in laying before you as briefly as I can the results of laboratory investigations on the reaction of various elements of the nervous system to toxic agents. In doing this I shall confine myself almost entirely to the motor structures on account of their special relation to the questions at issue, but shall include for the same reason voluntary muscle which is inseparably and importantly connected with those structures.

MOTOR CELLS.

The large Betz cells of the motor cortex, the anterior horn cells of the spinal cord, the cells of various motor cranial nerves, such as the hypoglossal and the facial, as well as those of the nucleus ambiguus, belong to the same "stichochrome" class, and have been specially studied by many observers with reference to their modes of reaction to toxins. The method of Nissl has been the one almost uniformly employed and the results obtained by this method have practically become the standards of cell change.

There are important points to be remembered in connexion with the alterations in cellular structure. In the first place cell changes which are produced by toxins cannot be certainly distinguished from those which are the result of other influences. The term "axonal reaction" is applied to those changes which take place in the cell body soon after its axis-cylinder process has been divided or torn or subjected to some destructive or degenerative influence, and indicates a cellular condition which closely resembles that produced by toxic agents. In estimating cell changes, therefore, in toxic conditions it has always to be carefully considered how far they are dependent on the direct action of the toxin on the cells themselves and how far they are representative of "axonal reaction," due to the destructive or degenerative influence of the toxin on their axis-cylinder processes. It must, however, be conceded that very marked and even fatal cell changes can be produced by toxins independent of axonal reaction. A conspicuous example of this is seen in acute diphtheritic toxæmia in cases which have died from cardiac failure during the early stage of the disease. Bolton has recorded in this condition acute degenerative changes in the cells of the nucleus ambiguus associated with no demonstrable alteration in the vagus nerve.

In the second place the changes produced in the microscopical appearance of nerve cells under the influence of high temperatures and of artificial anæmia have been extensively studied by Sarbo, Mott, Ballet and Dutil, Goldscheider and Flatau, Marinesco, and others. The cell appearances, under these two conditions, are often not widely dissimilar at certain stages, and sometimes not unlike those produced by toxic agents. The frequent association of toxæmia with pyrexia necessitates, therefore, critical consideration of the relative potency to be attached to those two factors in the causation of structural changes in the nerve cell.

Finally, it is stated by F. Pick, van Gehuchten, Gordon Holmes, and others that unusual cellular activity is also associated with modifications of the histological cell picture which resemble some of those I am about to describe in toxic conditions.

Viewed in the light of the Nissl method, which depends for its usefulness upon the affinity displayed by certain parts of the cell for the basic aniline dyes, the large multipolar motor cells of the central nervous system may be regarded, arbitrarily, as composed of two substances. The one substance is stained by the basic dye, is basophilic, and may be called chromatic; it is found in the nucleolus, the nuclear membrane, and in certain masses which lie within the protoplasm of the cell body and its dendrites and which have been variously termed Nissl bodies, chromatin granules, or tigroid. (Figs. 1 and 2.) The other substance is unstained by the Nissl method on account of its non-basophilic or acidophilic properties and may be called achromatic. According to the researches of Held, Ramon y Cajal, and others, who have employed special methods for its detection and study, this achromatic substance is found throughout the cell body and axis-cylinder process in the form of a fine reticulated granular network, in the meshes

of which are seen the chromatin granules. A substance of somewhat similar reaction is also found in the more central parts of the nuclear body and in the very centre of the nucleolus. This achromatic material is probably the essential part of the cell protoplasm. To complete the picture of a normal cell of this class stained by the Nissl method it has only to be remembered that its shape is polygonal, with concave borders between the bases of the processes; that the nucleus is round, generally central in position, with a centrally placed nucleolus; and that the chromatin granules in the cell body are variable in size and shape but are usually arranged along pericentric lines roughly parallel with the cell borders. Lastly, it must not be forgotten that a mass of greenish-yellow pigment is normally present in many cells, certainly after 20 years of age.

ACUTE TOXIC CELL CHANGES.

Under this heading we have to deal with a variety of appearances and it is difficult to say for certain in what way they are related one to another.

Early types.—1. The cell has hardly altered in shape but the concave borders have become straight or slightly convex; the nucleus is central and perhaps a little swollen; the chromatin granules in the cell body are breaking up into finer particles either in patches or, more commonly, around the nucleus (perinuclear chromatolysis), or near the periphery (peripheral chromatolysis). (Fig. 3.) 2. The cell is swollen moderately, the nucleus is central, and rather enlarged. The whole cell body is stained somewhat deeply probably owing to the fact that the chromatin bodies have broken up into fine particles and that the achromatic substance has become more basophile. The contrast between the chromatic and achromatic parts is consequently much less marked and the staining of the achromatic substance renders the cell processes more distinct and more easily traced away from the cell. (Figs. 4 and 5.)

Moderate type.—This type may probably be secondary to either of the early types. (Fig. 6.) The cell is round and swollen; the nucleus is displaced from the centre, is often less spherical, more oval or reniform in shape, and contains an excentric nucleolus. There are no longer any chromatin granules in the cell body or only a few remnants may be seen on the periphery, in the bases of the dendrites, or, in other cases, close to the nucleus (complete or almost complete chromatolysis). The cell protoplasm takes on a pale homogeneous or faintly granular stain, which, if the process continues, becomes less and less evident. Up to this stage it is practically certain that recovery may take place under favourable conditions.

Advanced types.—1. The cell is globular in shape with few or no distinct processes, the nucleus, with wrinkled or distorted membrane, has appeared on the surface and is on the point of being extruded or is actually outside the cell; the cell body presents a pale homogeneous and sometimes rather vitreous appearance with no trace of chromatin granules. (Fig. 7.) 2. More rarely the cell has retained something of its original shape with an irregular outline, but the whole cytoplasm, together with the nucleus, is of a uniform lustreless colour, the nucleolus alone standing out on account of its somewhat deeper hue. The first of these two advanced types must be regarded as fatal as soon as the nucleus and cell body are parted. The second probably represents a fatal coagulative change which in many respects resembles that produced by exposing cells to a high temperature.

In association with the moderate and advanced types of alteration it is not by any means unusual to find vacuoles in the cell protoplasm and, more rarely, fissures have also been described. Cell conditions such as I have briefly put before you have been recorded in experimental intoxication with various poisons.

In human pathology analogous conditions have been found in alcoholic, diphtheritic, and other forms of poisoning. Recently Poynton and Gordon Holmes have described widespread changes of the same character in rheumatic chorea.

From these facts concerning acute toxic cell change we can deduce two important points. In the first place, the histological appearances are not absolutely distinct from those produced by other influences. In the second place, no poison can be said to evoke an anatomical cell change which is different from that evoked by other poisons. In other words, there is no specificity in the microscopical evidence of toxic influence.

The methods of Ramon y Cajal, of Donaggio, and others

for the purpose of bringing out the neuro-fibrils have been successful in the hands of their inventors and of Marinesco, Genté and Bellot, and others, in showing that these fibrils undergo marked changes in toxic and other conditions, but the consensus of opinion at the present time favours the view that they are only present when the Nissl changes can also be evoked and are in no way more specific.

ACUTE TOXIC CHANGES IN NERVE FIBRES.

The Marchi method (or the "Busch" modification) is that most commonly employed for the purpose of demonstrating early changes in the nerve fibre and its myelin sheath. In acute toxic states I believe that there are two different conditions to be met with: 1. The myelin sheath undergoes a change which is practically indistinguishable from the Wallerian degeneration of a nerve fibre separated from its nutritional centre. For example, I may cite the case of a man dying from acute pneumonia who at the time of his being taken ill was undoubtedly suffering from the very earliest stage of alcoholic neuritis. In the peripheral parts of his anterior crural and external popliteal nerves I found early Marchi degeneration. Most fibres were normal, others showed a faint brown tint, generally more marked near a node, and others had become more deeply stainable from node to node in their entire breadth. This condition was not secondary to cell change since the ganglion cells were nearly all normal, or if changed only very slightly so, but must be regarded as a degenerative reaction on the part of the myelin sheath to a true toxic change of the axis cylinder. In more advanced stages of the same process the altered myelin breaks up into large rounded masses which are taken up by various cells and ultimately absorbed. This represents the *Wallerian fatty degeneration* of toxic origin and may be seen in the central nervous system as well as the peripheral nerves, although it is more common in the latter. I believe that when this occurs there is always some interference with the function of the fibre, although I do not deny that function may be regained before the myelin sheath is completely restored to its normal condition. 2. Another result of acute toxic states is the appearance in the central nervous system or the peripheral nerves of more or less numerous fine rounded drops of fat or material which is at any rate stained by the Marchi method. These are common in the white matter of the lateral and anterior columns, of the posterior columns, especially in the column of Goll; and are more frequently seen in the posterior than in the anterior roots. If examined under a high power, either in transverse or longitudinal sections, they are seen to lie mostly within the myelin sheaths but are seldom large enough to fill more than a half of the transverse diameter of any particular fibre. They appear singly or in short rows of two, three, or four together and vary in their depth of staining. When these are present in the white columns it is usual to find still finer fatty particles scattered in the grey matter of the anterior horns, and occasionally in that of the cerebral cortex. This condition I have often observed in toxic states of all kinds, and a good example

Fig. 10.—Sections from cardiac muscle in a case of acute ptomaine poisoning dying in 36 hours. Extensive fatty change, which was also present in the diaphragm and to a less extent in the skeletal muscles. Stained by Busch method.

Fig. 11.—Transverse section of small vessel in the cortex cerebri, showing marked fatty change in its walls. Stained by Busch method.

xic states in which paralysis is not a part of the symptomatology? With the object specified in view a number of cases of general toxæmia were examined in the following manner: the motor cortex by the Nissl, van Gieson, and Busch methods; parts of the pons, medulla, and spinal cord by the same methods; and portions of the heart, diaphragm, and vastus internus muscles, together with their intramuscular nerves by the van Gieson, Busch, and charlach red methods. The cases included (1) a case of ptomaine poisoning fatal in 33 hours, with a temperature rising from 99° 6' to 107° F. just before death; (2) a case of septicæmia, culminating in general peritonitis, of three weeks' duration with an irregular temperature of the septic type; (3) a case of erysipelas of the face complicated by myocardial degeneration and granular kidney in which the erysipelas was present for a week with a temperature varying between 100° and 102° 2'; (4) a case of extensive surface burns with septicæmia and fatal hæmorrhage from a duodenal ulcer (temperature 102° to 103° during one week); (5) two cases of acute infective enteritis, one fatal in two or three days and the other improving temporarily with a fatal relapse at the end of 17 days; (6) two cases of acute periosteitis with general pyæmia, one fatal at the end of 20 days, with a temperature varying between 99° and 104°, and the other fatal in three days with a temperature of from 101° to 102°; (7) a case of acute pulmonary tuberculosis dying after a short illness in which the symptoms were only prominent during the last 19 days (temperature 99° to 102°); (8) a case of acute lymphatic leukaemia of probably three months' duration, but with a very acute termination (temperature during the last four days 102° to 104°); (9) a case of measles, the patient dying from broncho-pneumonia in a week (temperature 101° to 104°, rising to 107° just before death); (10) a case of diphtheria, death resulting from broncho-pneumonia after three days' illness (temperature 100° to 102°); and (11) a case of acute diabetes in a man, aged 23 years, the symptoms persisting for three weeks and the patient dying comatose (post mortem there were found large white kidneys and ulceration of the colon). In addition to these cases I have examined on the same lines two cases of pneumonia with unsuspected meningitis.

The intense fatty change in the heart and diaphragm and less marked change in the vastus internus in the acute ptomaine poisoning case I have already referred to, and I have only to add that the Betz cells of the motor cortex showed what I have described as the second early type of change—namely, slight general swelling of the cell with somewhat diffuse staining of the chromatic and achromatic substance. The cells of the medulla and cord showed no change but the myelin of the latter presented diffuse fatty change of the non-Wallerian type. In the case of erysipelas the nervous tissue showed no changes. The cortical vessels were fatty and not only the heart but the diaphragm and vastus internus were full of fine fatty particles, whether the result of the erysipelas or associated with the myocardial degeneration and granular kidneys is not quite clear. In both cases of staphylococcal pyæmia there were early changes in the Betz cells but no alteration of the bulbar or spinal cells, slight diffuse fatty degeneration of the myelin and of the cortical vessels, but no evidence of disease in the muscles except in one case where the heart and diaphragm showed fatty change in the neighbourhood of a purulent pericarditis. It is worthy of note that in neither of two cases of acute lobar pneumonia was meningitis suspected during life, although it was apparent to the naked eye all over the cord and brain in the one and very evident on microscopical examination in the other. These cases of meningitis were the only instances in which definite changes were found in the cells of the cord and medulla. In one case of pneumonia there were slight fatty changes in the vastus internus associated with a normal heart and diaphragm. On the other hand, extensive fatty degeneration of the diaphragm was present in the case of measles and broncho-pneumonia and in the case of acute pulmonary tuberculosis, although the heart and vastus internus were free from fat in both instances. In one acute case of infective enteritis the cells of the cortex were very little changed, although the cell bodies appeared small in proportion to the size of the nuclei. In the other case of longer duration the nuclei were swollen and the cytoplasm showed some chromatolysis. In neither were there fatty changes in the central nervous system or muscles.

It is not right to attach much importance to such a

limited number of cases, but it may be noted that in eight out of 13 cases very early changes were observed in the Betz cells of the cortex, although no changes were found in the cells of the medulla or cord. This seems to point to a greater susceptibility on the part of the more highly developed cells to toxic influences and is in accordance with the clinical picture of easily exhausted voluntary effort frequently seen in toxæmic states. The absence of changes in the nuclei of the medulla makes one wonder whether we are not inclined to attribute disturbances of respiration and circulation too often to bulbar intoxication and whether it is not some higher respiratory and cardiac centre which is sometimes to blame. While on the one hand diffuse fatty myelin change was common in the series, that form of degeneration which resembles the Wallerian variety was only seen, and that scantily, in the case of septicæmia of three weeks' duration. The importance of this result lies in the warning it provides that we should not be too ready to regard this diffuse type of myelin change as explanatory of marked functional disturbance in the form of paralysis or loss of sensation.

With regard to muscular fatty changes this investigation serves to show that the diaphragm is even more liable to undergo this form of degeneration than the heart and that both are much more commonly affected than the vastus internus which was taken as a type of ordinary skeletal muscle.

Finally, I must draw your attention to the fact that in no single instance did there appear to be any evidence of perivascular cellular infiltration or neuroglial proliferation. Indeed, the only vascular phenomenon beyond engorgement of vessels, which was certainly marked in many cases, was the occurrence of increased amounts of fat in the vessel walls or sheaths, especially in those of the cortex cerebri.

THE PATHS BY WHICH BACTERIA OR THEIR TOXINS MAY REACH THE CENTRAL NERVOUS SYSTEM AND THEIR MEANS OF DISSEMINATION WITHIN IT.

When we come to inquire into the pathogenesis of the acute toxic paralyses it will be necessary to take into consideration the paths by which the central nervous system can be brought within the sphere of action of bacteria and their toxins and further to recognise, as far as we can, along what lines the noxious influences can spread within the system. Excluding direct invasion from neighbouring diseased tissues there are obviously two definite channels about which it is advisable to say a few words. These are: (1) the blood, and (2) the lymph.

1. *The blood supply of the central nervous system.*—This is arranged, as one would expect, so that the richest vascularisation is associated with the presence of the most active elements or ganglion cells, whereas the more passive conducting paths are content with a somewhat poorer portion. In the spinal cord the largest artery is the anterior spinal which supplies the greater part of the cellular grey matter and which is of larger calibre in the cervical and lumbar enlargement, where the cells are numerous, than in the dorsal region where they are relatively few in number. The smaller pial vessels supply the white columns but do not provide such a rich capillary network as is found in the grey matter. These arteries derive their supply from the anterior and posterior spinal arteries with reinforcement from each of the spinal root vessels. The great length of the segments in the middle third of the dorsal region and the lack of large reinforcing root arteries probably render that particular portion of the cord less vascular than any other, and it is here that true vascular thrombosis is most often met with. It appears from the injection researches of Kôdyi that there is no definite anastomosis between the area supplied by the anterior spinal artery and that supplied by the pial vessels and that there is a zone in the neighbouring borders of the white and grey matter which is partly vascularised by the one and partly by the others. It would seem therefore that the grey matter of the cord with its rich capillary network, and especially that of the cervical and lumbosacral enlargements, is more lavishly exposed to circulating toxins than the white matter. The occurrence of emboli in the cord in human pathology is a rare event owing to the somewhat tortuous route and small calibre of the arteries, but Leyden in two cases of ulcerative endocarditis found purulent foci scattered indiscriminately through the white and grey matter of the cord. Cressier found metastatic abscesses more frequently in the grey than

is afforded by the case of a woman who died after three weeks of puerperal septicæmia culminating in general peritonitis. The necropsy was made six hours after death and the brain and cord were hardened by the usual formalin method. The above described fatty change was found throughout the white matter of the brain and spinal cord and Fig. 8 shows a longitudinal section of the spinal cord taken at a spot where there happens to be a fibre undergoing true Wallerian degeneration by way of contrast. Only a very few of the latter type were seen and they may be regarded as more or less accidental. I have little doubt that this particular form of fatty change in nervous tissue may be increased by lengthening the interval between death and the fixation of tissues. Whether this is so or not I am quite convinced that the appearance I have alluded to indicates an ante-mortem change, or is at any rate promoted by chemical processes occurring during life.

The view which I have adopted concerning this production of droplets which stain with osmic acid is that it is a fatty degeneration of the myelin, in some ways analogous to the fatty change found in other organs in toxic conditions and is by no means necessarily an evidence of loss of function on the part of the nerve fibres the sheaths of which are affected. Some stress should be laid on this point, I think, because a sufficiently distinct line has not always been drawn between these two different forms of fatty change. Their differentiation is rendered much easier and clearer by the examination of longitudinal than of transverse sections of the spinal cord or nerves.

With regard to the axis cylinders themselves it is well recognised that under toxic influences they may appear swollen and more deeply and diffusely stained by various reagents, noticeably by hæmatoxylin, in ordinary logwood or *vaa Gieson* preparations. An irregular vacuolation of the axis cylinder similar to the vacuolation of the ganglion cell protoplasm has also been described.

ACUTE TOXIC CHANGES IN MUSCLE.

There has been much investigation into and much written about the various forms of degeneration which take place in muscles in acute infective and toxic conditions, but we are concerned here only with the early histological alterations. These may be regarded as of two varieties, either of which may be present alone or combined with the other in striated muscles.

The first is a condition which can be recognised when sections of muscle are stained by the ordinary logwood or van Gieson methods. It has been termed diffuse hyperplasia and is characterised by the fact that the muscle fibre swells, so that its transverse diameter is increased and its longitudinal outline often rendered sinuous. In transverse section it appears more rounded and less polygonal in shape and when seen in longitudinal sections it has generally lost much of its distinct transverse and longitudinal striation. It tends to take a somewhat different, generally more yellow, colour in eosin preparations and to present an appearance which is best described as slightly vitreous. These alterations in the sarcoplasm are often associated, even in very early stages, with a swelling and proliferation of the sarcolemma nuclei and with the presence of an increased granularity of the plasma.

The second type of change is one which is microscopically evident only when methods for detecting fat are used in the preparation of the tissue sections. Fatty change is probably the most suitable name to apply to it because it has been shown both by Rindfleisch and by Dudgeon that it is not due to an increase of fatty content of the muscles but to a chemical change by which fat, previously present in a saponic form, becomes demonstrable by the osmic acid, Schärlach red, or Sudan III, methods. The fatty change is first apparent around the nuclei of the fibre but is soon rendered conspicuous by the appearance of fine droplets arranged in rows between the fibrils, producing at first an intensification of the normal striation. (Fig. 9.) As the droplets increase in size the transverse striation of the fibre tends to become less easily perceived, but in other respects the fibre may retain its normal features. It is probable that this fatty change is, like the hyperplasia, quite remediable under favourable conditions. As I have said before, the fatty and hyperplastic changes may be associated in one fibre, and, following the rule of all toxic changes, it is usual to find many normal fibres lying among those which are affected by one or other or both morbid processes.

The change which I have now described is not very uncommon in a great variety of toxic states, but it is due to Dudgeon that we are cognisant with its extremely early presence in the diaphragm and heart in cases of experimental acute diphtheritic toxæmia. Mott has told us in his Croonian lectures that fatty change of the heart and striated muscles is a striking feature in animals poisoned by the bacillus botulinus, and I found the same condition in a fatal case of ptomaine poisoning which was under my care at the Royal Free Hospital last summer. (Fig. 10.)

It is still more important to note that this fatty change of muscle can be, and is, frequently present without alterations in the nerve fibres as shown by Bolton and Dudgeon. I have been able to confirm the same principle in the case of a man who died from the effects of a fracture dislocation of the dorsal spine with resulting compression paraplegia. In the course of examining him between the time of his accident and his death I was surprised to find some slight paresis of the extensors of his wrist and of his supinator longus muscle, which, of course, could not be explained by the spinal lesion. On ascertaining that he was a potman and that he was in the habit of taking the first liquid refreshment from the bar-taps I attributed the muscular weakness to early lead poisoning. After death I found intense fatty change in the supinator longus, whereas there was none in the flexor brevis pollicis. The musculo-spiral nerve was free from any change with the exception of a few scattered drops of altered myelin. In the same case it is interesting to note that the heart was normal while the diaphragm showed fatty change in at least 80 per cent. of its fibres. We may assume, with a tolerable degree of certainty, that in toxic conditions muscles may undergo fatty change of a primary kind, although the same change is observed as a secondary condition in cases of peripheral nerve degeneration.

I propose to leave for later consideration the very important question of vascular change in toxic and infective conditions of the nervous system, a question which is fraught with all the difficulties surrounding the meaning of the simple word "inflammation"; at this moment I will only refer to one small point.

Under normal conditions the adventitial or perivascular sheaths of vessels ramifying in the substance of the brain or cord may contain droplets of fat or granules of pigment. In all sorts of toxic conditions this fat may be largely increased in amount so that the vessel walls stain a deep black in Marchi preparations and the fine capillaries can be seen in places to be outlined by minute black fatty particles (Fig. 11). I must hasten to add that I am not referring to cases in which there is a general breakdown of the myelin sheaths and in which the fat so produced is carried by various wandering cells into the perivascular lymphatics and thence absorbed into the blood stream. The appearance which I refer to is present in cases in which there is no general myelin degeneration and is probably explained in one of two ways: (1) the fat may be the result of chemical changes in the elements of the vessel walls produced by toxins in the blood; or (2) it is abstracted from the nervous substance immediately surrounding the vessels.

CHANGES FOUND IN CASES OF TOXÆMIA NOT ASSOCIATED WITH MARKED NERVOUS PHENOMENA.

Some time ago it appeared to me necessary for the proper consideration of the pathology of the acute toxic and infective conditions of the nervous system that I should satisfy myself as to the changes present in cases of fatal toxæmia which are not commonly classified as nervous. It is of course impossible to draw a distinct line between nervous and non-nervous toxic states in that the symptoms of most acute toxic cases are largely referred to disorders of function on the part of the nervous system, but it is of some importance to know how far these clinical disorders of function are represented anatomically by variations in structure demonstrable under the microscope. Is the increased exhaustibility of the patient in voluntary movement the result of changes in the upper or lower motor neurons or of changes in the muscles? Are the disturbed actions of the more vital organs of circulation and respiration referable to changes of central origin or to change in the organs themselves? These and other questions, too numerous to specify, naturally occur to one. For my purpose, however, an entirely different question is the most momentous. How far are the paralytic symptoms in cases of acute toxic paralysis to be explained by the morbid changes found after death, or how far are these morbid changes common to other

The Hunterian Lectures

ON

THE RENAL FUNCTION IN ITS RELATION TO SURGERY.

Delivered before the Royal College of Surgeons of England,

By J. W. THOMSON WALKER, M.B.,
C.M. EDIN., F.R.C.S. ENG.,

HUNTERIAN PROFESSOR OF SURGERY, ROYAL COLLEGE OF SURGEONS
OF ENGLAND; ASSISTANT SURGEON TO THE NORTH-WEST
LONDON HOSPITAL AND TO ST. PETER'S
HOSPITAL FOR STONE.

LECTURE I.

Delivered on March 1st, 1907.

[The lecturer stated that he would confine his remarks to the subject of diagnosis and after referring to the pioneer work of Simon, Annandale, Morris, Hahn, and Czerny, he briefly sketched the cases in which information as to the renal activity was necessary. The subject was considered under two divisions: (1) the estimation of the total renal function; and (2) the estimation of the function of one kidney. He proceeded:]

1. THE ESTIMATION OF THE TOTAL RENAL FUNCTION.

Until a comparatively recent date the surgeon has been content to rely upon the symptoms and local signs of renal disease and the examination of the urine in order to judge of the activity or the reverse of the kidneys. I shall not dwell upon these. The kidneys may be exposed by operation and examined with a view to estimate the renal function. Palpation of the kidneys by the abdominal route has fallen into disuse from its unreliability. The exposure and examination of the kidneys by lumbar incision where the stability of the renal function is in doubt involve a risk which the surgeon may wish to avoid. And, moreover, it is not always easy to judge of the functional power of a kidney so exposed. In a case of suppression of urine following an operation upon a stricture I cut upon the kidney and stripped the capsule in the hope of relieving the renal tension that is supposed to exist in these cases. The kidney was flabby, and except for venous congestion did not differ in appearance, size, or consistence from a fully functional kidney. It is possible that some method may be developed by which fully functional kidney tissue can be recognised.

In a case of exploration of the kidney where I had used the methylene blue test for the purposes of diagnosis, and where the blue colour of the urine was still strongly marked, I hoped to find on incising the kidney that the exposure to air would produce the blue colour observed in animals that are passing methylene blue, and that I should thus be able to recognise the extent of the fibrous changes in the renal substance by the variations of staining. I was disappointed, however, for no change in colour was observed. Nor did the use of peroxide of hydrogen as an antiseptic during the operation bring out the colour.

I shall at once pass to the consideration of certain methods of estimating the renal function which have been introduced at a comparatively recent date.

Although it cannot be said that the physiology of the renal function is fully known, certain phenomena are recognised as being either a part of the function or inseparably connected with it. 1. The kidneys separate from the blood a fluid of different molecular composition—namely, the urine. The osmotic pressure of the urine is greater than that of the blood and the work performed by the kidney may be measured by estimating the osmotic pressures of these two fluids. This is conveniently done by investigating the freezing point of these fluids (cryoscopy). 2. The kidneys exercise a selective power by which certain substances are removed from the blood. Thus certain of the constituents of the urine do not appear in other secretions of the body, although they circulate in the blood. In similar manner certain foreign substances introduced into the blood are eliminated by the kidneys. Thus iodide of potassium, uric acid, and certain dyes, such as methylene blue, fuchsin, and resorcinol, may be recognised in the urine by the changes in colour which they produce. The kidneys are also said to

have the power of removing certain toxic bodies from the circulation, the accumulation of which would produce the syndrome of uræmia. 3. It is further recognised that the kidneys have a synthetic action in regard to at least one substance (hippuric acid) which exists in small quantities in the urine and they are thus brought into line with glandular organs. It is known that the administration of phloridzin is followed by the temporary appearance of glucose in the urine and that the glucose is produced by the vital action of the kidney. 4. Finally, a controlling function over nitrogenous metabolism by means of an internal secretion has been suggested by certain experiments. The methods of estimating the renal activity which follow are dependent upon the examination of some of these functions.

1. The Kidney as a Filter: (a) Cryoscopy.

Dresser¹ has shown that the osmotic pressure of the urine is considerably in excess of that of the blood. If the kidneys are diseased their power of bringing about a change in the osmotic tension of the fluid passing through is reduced and the freezing point of the urine is raised. The credit of introducing this method into clinical medicine belongs to Koranyi of Budapest.² Koranyi has advanced a theory of renal secretion upon which several tests are based. This observer suggests that a solution of sodium chloride filters from the blood into the renal tubules at the glomeruli. As this solution passes down the tubules it is concentrated by the absorption of water, and an interchange of molecules between the solution and the blood takes place through the renal cells. Each molecule of sodium chloride which is passed from the urine into the blood is replaced by a molecule of a different nature, such as urea, uric acid, &c., derived from the blood.

The following methods are based upon the estimation of the molecular content of the urine and the blood by measurement of the freezing point:—

Cryoscopy of the urine.—The freezing point of the urine (point Δ U) represents the molecular concentration of the fluid without reference to the nature of the dissolved substances. In the healthy state it is liable to considerable variations. Koranyi places it between -1.30° and -2.30° C. Copious libations may raise it to -1.0° and profuse sweating may lower it to -2.30° or under. In nervous polyuria it may rise to -0.17° C. In a large number of urines there is a precipitation of urates at the freezing point and this materially affects the calculation. The quantity of molecules thus thrown out of solution is a variable factor, so that no correction can be made which will apply to all urines. The mixing of alkaline and acid urines also induces changes in the freezing point. Apart from these fallacies, however, the variations in the freezing point of the urine are so considerable in the healthy individual that no trustworthy observations can be made by this method.

According to Koranyi's theory the number of molecules of sodium chloride in the urine will depend upon the interchange of urea, &c., which has taken place in the renal tubules. By dividing the figures of the freezing point by the sodium chloride content per 100 cubic centimetres of urine, Koranyi hopes to estimate the work of the renal epithelium. The figures work out at 1.7, or in a series of cases at 2 or over. The more rapidly the sodium chloride solution is hurried past the renal epithelium the less will be the interchange of molecules, so that the product of this formula is smaller. The volume of urine thus comes to be an important factor. Claude and Balthazard³ correct Koranyi's formula for both the volume and the total body weight and term the product the "total molecular diuresis." By calculation they ascertain from this the "diuresis of elaborated molecules," and after correcting this again for volume and weight they obtain the "sum of the molecular interchange" by the renal epithelium by dividing the former by the latter product. The accompanying chart (Fig. 1) shows in a graphic form a period of renal inefficiency in a case of chronic nephritis. The elaborate calculation thus entailed depends upon several factors each of which is liable to fallacy. It is known that there is a retention of chlorides in renal diseases and Claude and Mauté⁴ make use of this fact to observe the result of a measured administration of chlorides compared with cryoscopy.

in the white substance. Experimentally embolic softening in both grey and white matter has been produced by injecting fine particles into the lumbar arteries by Lamy and Rothmann. Singer injecting the vertebral artery produced infarcts in the posterior columns and horn of the corresponding side of the cervical cord. I shall have to make further reference to experimental embolism of the cord, especially in relation to Hoohe's work, when discussing the nature of acute poliomyelitis. With regard to the brain the same generous blood-supply is provided by means of a rich capillary network for the grey matter both of the cortex and of the basal ganglia, the white matter, on the other hand, being comparatively poorly off. In the brain stem the sharp line between white and grey matter is not nearly so distinct as it is in the case of the cerebral hemispheres or spinal cord, a fact which can be ascertained from a glance at any Weigert-Pal section of the medulla or pons, but nevertheless the parts with most cells are generally best provided with vessels. Embolism of the cerebral arteries is sufficiently common to require no comment here. Two facts stand out clearly from this short review of the general principles of blood circulation in the central nervous system: (1) toxins in solution in the general circulation will be brought into closer relationship with the grey than the white matter; and (2) solid particles capable of forming emboli are almost invariably carried into the larger cerebral arteries and very rarely into the cord. When embolic infarcts do occur in the cord they are found both in white and grey matter, perhaps with a little preference for the latter owing to the larger calibre of the anterior spinal artery.

2. Lymphatics of the central nervous system.—There is a certain amount which is known and a great deal which is speculative about the lymphatic supply of the brain and cord and anyone who wishes to inform himself about the subject had better for his peace of mind avoid reading more than one authoritative statement on the matter.

[After describing what is known about the lymphatic system of the spinal cord Dr. Buzzard proceeded:]

The connexion of the spinal lymphatics with other lymphatics, and more especially with those of the peripheral nerves, has next to be examined. Our knowledge on this point is derived largely from observations in human and experimental pathology. D'Abundo injected china ink into the posterior columns of dogs and found that the granules tended to spread up the cord and towards the central grey matter. They did not traverse the posterior horns into the ventro-lateral columns nor did they find an exit into the posterior roots. After injection into the central grey matter the ink granules spread more generally into the anterior, lateral, and posterior columns, but again chiefly in an upward direction. There was in either case a general tendency on the part of the deposit to find its way into the perivascular sheaths. Guillaumin more or less confirmed the results obtained by D'Abundo from experiments conducted on similar lines. He came to the conclusion that there were perivascular lymph sheaths and lymph spaces in the tissue, that the circulation was ascending, that the spaces in the posterior columns were independent of those in the antero-lateral, and, finally, that the central canal takes on the functions of a lymph channel. Sicard, on the contrary, did not find that granules injected into the posterior columns were confined to that region but tended to spread in all the columns and to reach the perivascular sheaths of the subpial and subependymal vessels. The same author found no spread of the ink when injected into the nerve roots; when injected into the cerebro-spinal fluid it was quickly disseminated throughout that liquid and gained ultimately the lymphatics of the body.

More important are the investigations which have been made on the mode of infecting the lymphatics of the spinal cord through the lymph channels of the peripheral spinal nerves. Marinesco examined the nerves and spinal cord in a case of gangrene of the leg and found evidence of an ascending inflammation along the nerve lymphatics to the cord, which was the seat of perivascular infiltration and degenerated-ganglion cells. David Orr has also investigated a case in which there appeared to be toxic infection of the cord along the neural lymphatics in the cervical region. Homen and Laitinen in a paper published in 1899 described the results of an investigation they had conducted on rabbits in connexion with this question. They injected streptococci or their toxins into the sciatic nerve or spinal cord of these animals and were in the former case able to

or their toxins up the sciatic nerve, along the nerve into the cord and its meninges. The path of travel was chiefly the lymphatic canal lying beneath the neurium of the nerve and spinal roots, and it was that the posterior root was more favoured in this than the anterior. Within 20 hours of the injection cocci could be seen between the spinal meninges in the neighbourhood of the entering roots. They spread in the meninges all over the cord even to the cerebrum. They entered the cord along the posterior median septum but also along sheaths of other radial vessels and along the posterior roots. They were even found in the central matter. The histological changes corresponded to the situation of the cocci. In the nerves the fibres degenerated there were leucocytic infiltration and proliferation of fixed cells of the endoneurium and neural sheaths. Spinal ganglia there were cell changes, although they were chiefly confined to their capsules. Small cell infiltration was referred to in the subdural sheaths of the roots and in the meninges. Within the cord the authors described degeneration of ganglion cells, hæmorrhages, and so liberation of neuroglial cells, and, in some of the cases small round cell infiltration of the capillaries and tissue grey substance. Similar infiltration was observed, especially in the immediate neighbourhood of the posterior septum, in other instances. When toxins were injected the nerves the pathological changes were identical with those produced by the bacterial inoculation. If the cord itself was the site of inoculation similar changes were found. The spread of infection appeared to follow the lines of the meninges and central canal chiefly in an upward direction. The authors regard the changes as being due to the toxins rather than to the bacteria themselves. Homen in a paper published in 1902 records a series of similar experiments carried out with the staphylococcus pyogenes, the diplococcus pneumoniae, bacteria coli, typhoid, &c. The animals which did not die spontaneously were killed at intervals varying from under 24 to three months after injection. The changes in these experiments were very similar to those I have just referred to, but it was noticed that the results with which the different bacteria spread in the cord and was variable. Thus the bacillus coli had a greater tendency to travel than the staphylococcus or cocci, especially in the spinal cord. Another point of interest lies in the fact that the space of time during which the various organisms could be detected in the tissues after injection varied not only with the microbe but also with the tissue examined. In the case of the streptococcal infections, for instance, in the course of a week or 10 days the cocci had disappeared from the spinal cord, whereas they were still evident in the nerves for about another ten days.

The important deductions to be made from these investigations are the following. 1. That organic and inorganic substances when present in the lymph spaces of nerves tend to be carried centralwards towards the spinal cord meninges, and especially through the posterior spinal roots. 2. Entry into the spinal cord is made chiefly along the various septa within the lymph channels of the nerve roots and along the anterior but more particularly the posterior roots. 3. That the same substances within the spinal cord and its membrane appear to travel upwards mainly between the meninges and along the central canal. 4. The changes within the cord resulting from its bacterial infection through these lymph channels are somewhat patchy and irregular, affecting the grey and white matter alike, with a special incidence on the posterior columns. 5. The morbid histological processes consist of toxic changes in ganglion cells, blood extravasations, small round cell infiltration of the tissues and perivascular sheaths, some liberation of neuroglial cells, and parenchymatous degeneration of the nerve strands.

UNIVERSITY OF GLASGOW.—The Senate of the University has resolved to confer the honorary degree of Doctor of Laws on the Prince and Princess of Wales and many other distinguished persons, among whom are Professor J. N. Collier, F.R.S., professor of organic chemistry, University College, London; Professor John C. Kendrick, Professor Alexander Moody-Stuart, and Donald MacAlister, the new Principal of the University. The degrees will be conferred on Tuesday, April 23rd.

record where a considerable delay was occasioned by renal lesions of an insignificant character. When the blue is delayed the chromogen is usually delayed also. Thus in two cases of malignant disease of the prostate without symptoms of renal disease methylene blue elimination was delayed three and four and a half hours and chromogen elimination 53 minutes and four and a half hours respectively. But, on the other hand, a normal commencement of chromogen may be observed when the blue is delayed. In a case of "fibrous prostate" methylene blue appeared in two and a half hours and chromogen in 15 minutes, and in a case of renal pain where the kidney had been explored three years previously the blue was delayed three and three-quarter hours and the chromogen appeared in 15 minutes. Where the blue does not appear in the urine at all the chromogen may appear late. In a case of pyonephrosis the chromogen appeared alone in one and a quarter hours and in a patient suffering from advanced bilateral pyelonephritis the chromogen appeared alone in one hour. An early onset (under 30 minutes) of elimination of blue has been observed by Bard¹⁵ in epithelial nephritis. This early appearance of blue has also been noted in some cases of hypertrophy of one kidney (Albarran).

2. *Duration of elimination.*—In a healthy subject the whole excretion of blue is said to be completed in from 35 to 60 hours. My own observations seem to show that this period

FIG. 3.

Elimination in healthy subject prolonged to fifth day. Blue shown by continuous line, chromogen by dotted line.

is too short. After the first wave of elimination had passed traces were observed in the urine during the fourth, fifth, and even on the sixth days in some healthy individuals. (Figs. 3 and 4.) In pathological conditions of the kidney the excretion may take place within those limits, but the duration is usually prolonged, more rarely it is shortened.

Shortened elimination.—An excessive quantity of methylene blue may be rapidly passed. This occurs, according to Bard, in parenchymatous nephritis. The shortened elimination may coincide with a considerable reduction in the quantity of blue eliminated. In these cases there is extensive disease of the kidneys. According to Achard and Castaigne¹⁶ this short elimination occurs at the period when the blue is present in the blood in greatest quantity, and

¹⁶ Des Néphrites Rénales, 1900.

Cryoscopy of the blood.—The freezing point of the blood is remarkably constant at -0.58°C ., and the point Δ of the serum is practically the same as that of the blood. According to Koranyi, where one kidney is inefficient no change is found in the freezing point, but where the function of both kidneys is impaired the freezing point of the blood is lowered. A freezing point of -0.57° to -0.58° indicates a reduction in the total renal function. This margin of reduction is, however, too small and a point Δ of -0.59° or

FIG. 1.

Period of temporary renal inefficiency in chronic nephritis (Claude and Balhazard).

-0.60° should be shown before bilateral disease is diagnosed. Kummel⁵ looks upon a freezing point of -0.60° as a contra-indication to nephrectomy, and he believes further that when the molecular concentration is normal there is no interference with the total renal function. In 16 cases of bilateral renal disease this observer found the freezing point of the blood was from -0.60° to -0.65° , and in one case it was -0.71° . In 11 cases in which nephrectomy was performed a freezing point before the operation of -0.58° was taken as a proof of a healthy second kidney. After the operation the remaining organ in all the cases continued to secrete a sufficient quantity of healthy urine, and the freezing point of the blood remained at -0.56° . In one case the freezing point before operation was -0.59° and after the operation -0.57° . It is undoubtedly, however, that a lowered point Δ of the blood to -0.60° may be found apart from lesions of the kidneys. In my own cases the method has proved trustworthy but the number of cases in which I have used it is small. In cases where the point was depressed I was able by other means, such as the methylene blue test or phloridzin glycosuria, to confirm the inadequacy of the renal function or the symptoms were such as to leave no doubt upon the subject. In a case of enlarged prostate I disregarded a freezing point of the blood of -0.66°C . as the symptoms of renal inefficiency were insignificant. The patient succumbed to suppression of urine after the operation. In another case where obstructive anuria was in progress the point Δ of the blood was -0.71°C .

Comparative cryoscopy of the urine and blood.—In the comparative cryoscopy of the urine and blood (Bernard⁶) the ideal method for the estimation of the work done by the kidneys would appear to be provided. The freezing point of normal urine is from -1.5° to -2° and that of blood serum -0.56° . The quotient of these will be 2.5 to 3.5 and when this figure diminishes we may conclude that there is a diminution in the permeability of the kidney. These figures are, however, affected in the same way as those of the urine alone. The wide range of variation of the freezing point of the urine in health will disturb the figures considerably. Bernard has endeavoured to correct this fallacy by introducing the volume of the urine in cubic centimetres into the calculation. The figures thus obtained will vary in normal

individuals from 3000 to 5000. If we test this method on two types of cases—namely, a case of polyuria from interstitial changes in the kidneys the result of an enlarged prostate and a case of obstructive oliguria almost amounting to anuria—it will be found that the products of these formulae successfully show the impaired function when oliguria is present, but fail to demonstrate the condition where polyuria is present.

(b) Method of Wright and Kilner.

Wright and Kilner⁷ have taken advantage of the fact that complete destruction of the red blood corpuscles (haemolysis) occurs at a certain point of dilution of the blood serum and under similar conditions in a suspension of blood corpuscles in urine, and use this as an indication of the dilution of these fluids. The result is expressed in the number of dilutions required to bring about the haemolysis.

(c) Electrical Resistance of the Urine.

Aqueous solutions offer a variable resistance to the passage of an electrical current according to their composition, and Bordier of Lyons⁸ has applied this method to the examination of the urine. The urine owes its conductivity almost entirely to its mineral constituents and not at all to its organic contents. According to Dr. Dawson Turner⁹ the results of this method in renal disease correspond very closely to those of cryoscopy.

2. The Elimination of Certain Substances in the Urine.

It has long been recognised that the elimination of certain substances in the urine is hindered by disease of the kidneys. This subject has received the attention of Hahn, Rayer, Roberts, Duckworth, and others. Achard and Castaigne¹⁰ in 1897 introduced methylene blue as a drug on which observations might readily be made. Fuchsin was used with a similar object by Bouchard and Lepine¹¹ studied the elimination of rosaniline. Observations have also been made upon the elimination of iodide of potassium and the subject has been reviewed by Lafaye,¹² while Eée,¹³ Chopin,¹⁴ and others have studied the elimination of salicylate of sodium.

(a) The Methylene Blue Test.

If methylene blue be administered in the form of pill or injected into the muscles the urine will, after a time, assume a blue or green colour. Intramuscular injection is preferable on account of the greater accuracy. Methylene blue is absorbed into the blood from the point of injection as a colourless derivative and this reduction takes place only by the action of living tissues. Microscopical examination of the blood shows no colouration of the plasma or of the white corpuscles and the spectroscope shows no change. Nor can this leuco-derivative be detected in the blood by the means by which it is demonstrated in the urine. The colourless derivative or chromogen is transformed into methylene blue by the liver and the kidneys and is excreted in the bile and the urine. The blue in the bile is apparently re-absorbed in the intestine. Methylene blue is eliminated in the urine in two forms, partly as methylene blue and partly as a colourless derivative or chromogen. The latter is transformed into methylene blue by boiling with acetic acid. About 50 per cent. of the total quantity of methylene blue injected is eliminated by the kidneys in the first 24 hours, but only part of the total methylene blue is passed by the urine. The elimination of methylene blue in a healthy individual is shown in Fig. 2.

In studying the elimination of methylene blue there are several points which claim attention: (1) the commencement of elimination; (2) the duration; (3) the quantity of colouring material eliminated as blue and as chromogen; and (4) variations in the course of elimination.

1. *The commencement of the elimination.*—Chromogen appears in the urine 15 minutes after the injection and the blue usually commences in half an hour. This relation of chromogen and methylene blue was the rule in my cases in health and disease. In pathological conditions of the kidneys the elimination of blue is delayed and may occur after one or three or even several hours. Occasionally the blue does not appear at all. The period of delay is to some extent a measure of the severity of the renal lesion, but cases are on

⁷ THE LANCET, April 2nd, 1904, p. 921.

record where a considerable delay was occasioned by renal lesions of an insignificant character. When the blue is delayed the chromogen is usually delayed also. Thus in two cases of malignant disease of the prostate without symptoms of renal disease methylene blue elimination was delayed three and four and a half hours and chromogen elimination 53 minutes and four and a half hours respectively. But, on the other hand, a normal commencement of chromogen may be observed when the blue is delayed. In a case of "fibrous prostate" methylene blue appeared in two and a half hours and chromogen in 15 minutes, and in a case of renal pain where the kidney had been explored three years previously the blue was delayed three and three-quarter hours and the chromogen appeared in 15 minutes. Where the blue does not appear in the urine at all the chromogen may appear late. In a case of pyonephrosis the chromogen appeared alone in one and a quarter hours and in a patient suffering from advanced bilateral pyelonephritis the chromogen appeared alone in one hour. An early onset (under 30 minutes) of elimination of blue has been observed by Bard¹⁵ in epithelial nephritis. This early appearance of blue has also been noted in some cases of hypertrophy of one kidney (Albarran).

2. Duration of elimination.—In a healthy subject the whole excretion of blue is said to be completed in from 35 to 60 hours. My own observations seem to show that this period

FIG. 3.

FIG. 2.

Elimination in healthy subject prolonged to fifth day. Blue shown by continuous line, chromogen by dotted line.

is too short. After the first wave of elimination had passed traces were observed in the urine during the fourth, fifth, and even on the sixth days in some healthy individuals. (Figs. 3 and 4.) In pathological conditions of the kidney the excretion may take place within those limits, but the duration is usually prolonged, more rarely it is shortened.

Shortened elimination.—An excessive quantity of methylene blue may be rapidly passed. This occurs, according to Bard, in parenchymatous nephritis. The shortened elimination may coincide with a considerable reduction in the quantity of blue eliminated. In these cases there is extensive disease of the kidneys. According to Achard and Castaigne¹⁶ this short elimination occurs at the period when the blue is present in the blood in greatest quantity, and

¹⁵ Gazette Hebdomadaire, 27th Mai, 1907, p. 434.
¹⁶ Des Fonctions Rénales, 1900.

when the quantity of blue in the blood fails the kidney does not allow it to pass through. This does not, however, explain cases where the blue fails entirely to appear in the urine or only shows as a faint trace, yet the chromogens are excreted in fair quantity during a varying period. It appears to me that the difficulty lies in the transformation of the chromogen of the blood into methylene blue and that the diseased kidneys lack this power.

FIG. 4.

Elimination in healthy subject prolonged to seventh day. Blue shown by continuous line, chromogen by dotted line.

Prolonged elimination.—With a reduced quantity of renal tissue in disease of the kidneys the elimination of blue is prolonged. This is observed to a marked degree in chronic interstitial nephritis where traces of blue may persist for from six to ten days and more, rarely so long as 15 days. Prolonged elimination is also observed in surgical disorders of the kidneys. I have observed the elimination of blue during a period of eight days and 17 hours in a man, aged 67 years, who suffered from enlarged prostate and interstitial nephritis (Fig. 5). Faint traces are sometimes passed for

FIG. 5.

Enlarged prostate, interstitial nephritis. Delayed, prolonged, and diminished elimination of blue with single intermission on sixth day.

several days in individuals whose kidneys are healthy. In a healthy subject I was able to detect traces of blue on the sixth and seventh days after injection. There had, however, been intervals of clear urine. In a slight degree of renal impermeability the duration of elimination may reach the normal figure, but faint traces of blue may be detected in the urine for several days after the main wave of elimination has passed. The total quantity eliminated may not, however,

differ greatly from the normal. Most frequently prolonged elimination coexists with a diminution in the quantity eliminated.

3. The quantity of blue eliminated.—For the purpose of quantitative estimation the chromogen must be transformed into blue in each specimen examined. The most accurate method is the comparison of the blue urine with a solution of blue of known strength, more blue being added until the depth of colouring is the same in both fluids. The yellow colour of the urine introduces a fallacy that is corrected by using the urine of the patient before the blue appeared and adding to this the standard solution of methylene blue. For purposes of comparison charts may be constructed which show the varying depth of colouring of the urine as the course of the elimination. The quantity of blue eliminated is diminished in diseases of the kidney. In advanced disease no blue may appear in the urine and under these conditions chromogen may appear for a short time and may be entirely absent. In one patient under my care no blue

FIG. 6.

Normal elimination of methylene blue and chromogen compared with quantity of urine during first 12 hours after injection.

appeared in the urine although no appreciable renal lesion was present. The patient suffered from bilharzia cystitis and took the methylene blue by mouth for its therapeutic effect. He took half a grain of methylene blue daily for a month and two grains daily for two months, but no trace of blue or chromogen appeared in the urine. In four other cases no blue was passed and each of these patients suffered from advanced renal disease. In two of these chromogen was passed and in two it was absent.

4. Course of elimination.—The elimination of blue rapidly rises and reaches its maximum about three or four hours after injection and remains at its highest level for four or five hours. It then falls gradually and after 30 or 40 hours has usually been reduced to a pale green tint. After this traces may be passed for some hours or even for several days. During the excretion a draught of water will cause a rapid diminution in the colour, but after an hour or so the urine resumes its previous hue. In Fig. 6 the relation of the

quantity of urine and blue is shown and the cause of elimination by hourly observations during the first 12 hours in a healthy individual.

The elimination may be intermittent. It may fall almost to vanishing point and rise again or it may disappear entirely and reappear later. Disturbances in the rhythm of elimination occur in functional disorders of the liver. They are also said to occur in compensatory hypertrophy of the kidney. In 46 cases of different diseases Asfal¹⁸ observed intermittent excretion in 60 per cent., and in half of these it was diurnal. In 61 cases under my observation intermittent elimination was present in 14 (23.3 per cent.). In six healthy individuals the elimination was intermittent in all. (Figs. 7 and 8.)

The value of the methylene blue test in surgical diseases.—I used the test on six healthy adult men who volunteered

FIG. 7.

Intermittent elimination in a case of syphilis. No signs of disease of kidney. Blue shown by continuous line, chromogen by dotted line.

themselves for this service. In 55 cases injections of methylene blue were made for purposes of diagnosis. The dose in all these cases was the same—namely, 15 minims of a 5 per cent. solution of pure methylene blue.

These cases may be briefly summarised as follows. In some conditions which were unconnected with the urinary tract an unexplained delay in the commencement of elimination was observed. In inflammatory diseases of the bladder, where there was no reason to suspect renal changes, there was also a slight delay in the appearance of the blue. Cases of obstruction in the lower urinary tract invariably showed a delayed elimination. The average time of appearance of blue in 18 cases of obstruction was 3 hours 27 minutes. The delay was more marked where the obstruction was due to enlarged prostate than where it resulted from stricture. Thus, in eight cases of long-standing stricture the average time of commencement was two hours and 16 minutes, while in ten cases of prostatic obstruction the average delay was four hours and 25 minutes, and this did not include one case where no blue appeared. The duration of the obstruction did not sufficiently explain this difference, for the length of time during which symptoms of obstruction had been present was much greater in the strictures than in the prostatic cases. Nor was the degree of obstruction greater in the cases of prostatic disease. A similar difference was observed in the duration of the elimination of blue in cases of stricture and of enlarged prostate. The average duration in the former was 82 hours, not a very great increase over the normal figure, while in the cases of prostatic obstruction the average elimination continued for 118½ hours without taking the case of complete suppression of blue into consideration. In slightly damaged kidneys there was but little delay or prolongation, but where advanced renal disease was present there was delay, diminished and prolonged elimination. In severe bilateral renal disease the blue did not appear in the urine at all. There were altogether five cases in 61 where blue did not appear in the urine. One of these was

the case of bilharzia cystitis in which the kidneys were probably healthy and which I am inclined to look upon as a very unusual observation. The remaining four cases were—one case of urinary obstruction from enlarged prostate, one case of bilateral renal calculus, one case of pyelonephrosis with stricture of the urethra, and one case of pyelonephritis with abscess of the prostate and foul cystitis.

I operated upon three of these cases and refused operation in one. The patient with bilateral renal calculus who was refused operation died 18 months later from suppression of urine. Of the three cases that were submitted to operation two died. On one of these the operation was done to relieve a large collection of pus in the prostate when the patient was beyond hope of recovery. The other two cases were operated with the hope of cure. The patient with enlarged prostate showed no symptoms of renal inefficiency before operation. He was a spare, muddy-complexioned man who had suffered from complete retention of urine for some months. The urine had a specific gravity of 1010. There was an increased quantity of urine and the urea varied from 0.6 to 1.1 per cent. The temperature occasionally rose to 100°F. The operation presented no difficulty and the enucleation lasted three and a half minutes. After operation the urine gradually failed and the patient died on the fifth day. The patient with pyelonephrosis did not show any signs of failing renal function, but he was a heavy lymphatic man and a poor subject for operation. After nephrotomy he showed signs of commencing renal failure, but these passed off and similarly, after nephrectomy a fortnight later, there were vomiting, restlessness, distension, and diminished urine, but he recovered. The methylene blue test was again used after the nephrectomy. Blue appeared in the urine after one and a

FIG. 8.

Intermittent elimination in healthy individual. Blue shown by continuous line, chromogen by dotted line.

half hours and chromogen after one hour. The blue disappeared in 25 hours; the chromogen, which was present in greater quantity, pursued an intermittent course and disappeared in 53 hours (Fig. 9).

The value of methylene blue as an indication of the state of the renal function must be judged by a comparison with the information obtained from the symptoms and the examination of the urine. Three out of eight cases of stricture showed insignificant symptoms of renal inadequacy; in all the excretion of urea was large. In all of the cases there was delay and, in several, prolongation of blue elimination. The cases were selected as having suffered from intractable stricture for long periods and belonged to the class of case in which renal changes are common. In these cases the methylene blue appeared to be a more accurate test than the symptoms or the quantitative estimation of urea. In 11 cases of prostatic obstruction there were insignificant symptoms of renal inadequacy in three and fairly marked symptoms in one case. There were invariable delay and prolonged elimination of blue.

The cases already quoted of complete suppression of blue when no symptoms of renal inadequacy were present may be

taken as a type of the more accurate indication of the renal function by methylene blue. Further, the comparison of the result of the blue test in these prostatic cases with that of the stricture showing a less efficient renal function in cases of enlarged prostate than in stricture which was not shown by the symptoms is borne out by clinical experience of such cases. In two of the cases of kidney disease there were general symptoms of renal inadequacy; in one this was only continuous thirst, in the other the symptoms were well marked. In these cases no blue was passed. In the other two cases where no symptoms of renal failure were present and no blue was passed one died after the operation and had advanced interstitial changes in the kidneys and the other developed grave symptoms of renal failure after the operation, but these passed off. In one case there was a very marked improvement in the elimination of blue after the removal of a large pyonephrosis and this was attributed to the removal of a reno-renal reflex inhibition. The test is, I believe, one which is more trustworthy than the quantitative examination of the urea or the general symptoms of renal inadequacy. And this is especially the case in the more severe grades of kidney disease. In the slighter grades of renal disease the blue test appears to give results that are somewhat variable.

It has been urged in criticism of this method that the formation of chromogen introduces an element of uncertainty into the test. The chromogen should be converted into blue

and death after a varying interval. The lethal dose of normal urine for rabbits is stated at from 40 to 50 grammes per kilogramme of body-weight. Retention in the body, or increased excretion in the urine, of poisonous substances will cause variation in this dose. Most observers who have used the method agree that it is likely to afford useful information if the toxicity of both the urine and blood be examined, but that it is open to many fallacies and cannot be judged with mathematical exactness.

3. The Glandular Function of the Kidney.

Phloridzin test.

Mering²¹ discovered in 1885 that the injection of phloridzin caused a temporary glycosuria of a few hours' duration. The amount of sugar excreted does not depend upon the dose of phloridzin, provided sufficient of the drug be given to produce the maximal effect. The source of the sugar is apparently the tissue protoid. The phloridzin glycosuria is renal in origin as the experiments of Zaux,²² Biedl, and Kollisch²³ have shown. Klemperer²⁴ was the first to apply this method to clinical medicine. He showed that phloridzin glycosuria did not appear in cases of chronic nephritis. Achard and Delamere²⁵ introduced the drug as a test of the renal function and brought its use within the range of practical medicine. These observers showed that the sugar production was dependent upon the functional

FIG. 9.

Pyonephrosis. Chart of elimination of blue (continuous line) and chromogen (dotted line) after nephrectomy. Neither blue nor chromogen appeared in the urine in a previous test before nephrectomy.

when the quantity of the dye is estimated. The elimination of the blue by the liver appears to me to be a more serious disadvantage and one which cannot be overcome. Lépine¹⁹ has drawn attention to a fallacy which underlies observations on this and similar methods. The kidney does not eliminate all bodies without distinction in the same manner, and data obtained from the elimination of one body may not be reliable when applied to another. It is undoubted, however, that there is a certain parallelism in the elimination of different bodies and that the general permeability of the kidney for most bodies which it excretes is approximately similar to that of methylene blue.

(b) The Toxicity of the Urine.

Professor Bouchard introduced the method of estimation of the toxicity of the urine as a means of determining the efficiency of the kidney to eliminate the poisons produced by metabolism. This method attributes to the kidney as its most important function the removal from the blood of certain substances which, if retained, would cause uræmia.²⁰ The normal urine is highly poisonous but the exact nature of the poison is unknown. The injection of a certain quantity of urine into a rabbit causes symptoms of poisoning

activity of the kidneys, and any variation must indicate a departure from the normal functions of the kidneys.

Technique of the phloridzin test.—A subcutaneous injection of 15 minims of phloridzin solution (1 in 200) is made. This corresponds to five milligrammes of phloridzin. In a healthy individual sugar appears in the urine in from 15 to 30 minutes and the glycosuria continues for from two to four hours. The most important factor in the test is the total quantity of sugar eliminated. This varies from one to two grammes. The lowest limit of normal glycosuria lies between 50 centigrammes and one gramme and the highest from 2 grammes to 2.50 grammes. In the accompanying chart (Fig. 10) the normal course of the elimination of sugar after an injection of five milligrammes of phloridzin is shown. The curves of quantity of urine and urea also appear on the chart. Delay in the appearance of the sugar or prolongation of the elimination to five or six hours as slight traces are not signs of abnormal function.

Variation in the phloridzin diabetes of normal kidneys.—Achard and Delamere have shown that a diminution of the quantity of sugar eliminated (hypoglycosuria) or an excessive diabetes (hyperglycosuria) may take place without

FIG. 10.

NORMAL GLYCOSURIA.

Sugar shown as dark continuous line (S), urea as faint continuous line (U), and quantity as dotted line (Q). Observations made every quarter of an hour for one hour and every half hour after that.

anatomical changes being present in the kidneys. Normal hyperglycosuria is more frequently observed in healthy individuals than a diminished secretion of sugar. It has been met with under the most varying conditions, such as

FIG. 11

NORMAL HYPERGLYCOSURIA

Excessive quantity of sugar after injection of five milligrammes of phloridzin. Healthy subject. Sugar indicated by thick continuous line, urea by thin continuous line, and quantity of urine by dotted line.

typhoid fever, acute articular rheumatism, and bronchitis. In two healthy adults, under exactly similar conditions, the hypodermic injection of five milligrammes of phloridzin produced a glycosuria in the first which commenced in 15 minutes and lasted six hours, with a total elimination of

3.313 grammes of sugar (Fig. 11), and in the second a glycosuria which commenced in 30 minutes and lasted two and a half hours, and 1.039 grammes were eliminated (Fig. 10). The first was a hyperglycosuria, while the second was a normal glycosuria.

FIG. 12.

STRICTURE.

Diminished and delayed elimination of sugar in case of stricture.

Phloridzin test in renal disease.—The important variations found in renal disease are either a diminution of the quantity of sugar below one gramme or a complete absence of the sugar; a normal glycosuria has rarely been observed. Two examples occur amongst Delamere's cases,²⁶ and three cases are described by Jouffray.²⁷ Albarran has met with

FIG. 13.

ENLARGED PROSTATE.

Diminished and prolonged elimination of sugar in case of enlarged prostate.

several instances of marked hypoglycosuria with insignificant lesions of the kidney. This observer has also recorded instances of hypoglycosuria in unilateral renal lesions where the second kidney was functionally perfect by other tests.

²⁶ Thèse de Paris, 1899.

²⁷ Thèse de Lyon, 1903.

Among my cases was one of renal colic in which the total glycosuria amounted only to 0.53 gramme, and another of moveable kidney in which the glycosuria was 0.61 gramme. In two cases there was hyperglycosuria. In one I had recently removed a tuberculous kidney and there still remained severe tuberculous cystitis, but the solitary kidney was healthy. In this patient 5.21 grammes of sugar were rapidly eliminated, commencing half an hour after the injection. In the second there was chronic pyelonephritis more marked on one side. There were periodical exacerbations and the general symptoms pointed to a falling renal function. The patient passed 3.40 grammes of sugar in two hours. The quantity of sugar was diminished in cases of moveable kidney, renal colic, vesical calculus with slight pyelitis, enlarged prostate with interstitial changes in the kidneys, tuberculous kidney, and intermittent pyuria of obscure origin.

The value of the phloridzin test.—A diminished phloridzin glycosuria indicates in most cases disease of the kidney, and a complete absence of sugar should be regarded as a sign of advanced renal disease. The cases to which I have referred point in this direction and the conclusions were supported by other evidence. Sugar was entirely absent in four cases: a patient with a damaged solitary kidney after nephrectomy for pyonephrosis, another with obstructive oliguria which became anuria, and two cases of enlarged prostate with uroastasis. In these there were no symptoms pointing to renal inadequacy in the solitary kidney case and in one case of enlarged prostate. In the case of oliguria there was the diminished urine but no general signs at the time of the test, and in the enlarged prostate the signs of renal inadequacy were well marked—there were dry glazed tongue, thirst, headache, marked loss of flesh, loss of appetite, and nausea at times. The former case was under my colleague, Mr. J. G. Pardoe, and he kindly permitted me to examine the patient and to watch his progress. In the case of solitary kidney the patient had shown signs of renal inefficiency immediately following the operation of nephrectomy but these had subsided. The urea amounted to 1 per cent. and 1.2 per cent. on two separate examinations of 24 hours' specimens.

I have already referred to the case of enlarged prostate in considering the methylene blue test. The patient showed no symptoms of renal inefficiency with the exception of a moderate polyuria. The total urea excretion was well up to normal. No phloridzin glycosuria was observed. The patient died from suppression of urine after prostatectomy and his kidneys showed advanced interstitial changes and were hollowed from pressure. In the second case of enlarged prostate there were symptoms of renal inadequacy. After a period of bladder drainage the symptoms were less marked and the injection was repeated. On this occasion a reduced quantity (0.303 gramme) of sugar was eliminated. After prostatectomy the patient was drowsy for three days but his urine was plentiful and he made an excellent recovery. There was diminished glycosuria without symptoms of renal disease in several cases where it seemed improbable that the renal function could be impaired. Thus in a case of moveable kidney the excretion was 0.614 gramme. In obstruction from stricture (Fig. 12) or enlarged prostate (Fig. 13) there was diminution of the glycosuria.

Compared with the urea output and the general symptoms of renal inadequacy the phloridzin test was more delicate in these cases. The fallacy to which it is specially open is the pronounced effect which minor renal changes may produce upon the glycosuria. It is possible that this fallacy may be overcome by the use of larger doses of phloridzin, as Albarran has suggested.

I have indicated the fallacies and difficulties connected with each of these methods. As a measure of the total renal function the phloridzin and methylene-blue tests are most trustworthy. The phloridzin method is open to the objection that it is too easily influenced by slight variations in the renal function. At the present time the methylene-blue test is the method by which most trustworthy information can be obtained and appears to me to form a valuable addition to the clinical methods of estimation of the renal function.

Surgeon-Colonel P. B. Giles, V.D., F.R.C.S. Edin., Commandant Volunteer Ambulance School of Instruction, has been picked as high sheriff for the county of Bucks.

The Nettsonian Lectures

ON

THE DIAGNOSIS AND LOCALISATION OF CEREBRAL TUMOURS.

Delivered before the Medical Society of London,

BY CHARLES E. BEEVOR, M.D. LOND.,
F.R.C.P.,

PHYSICIAN TO THE NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, QUEEN-SQUARE, LONDON; AND THE GREAT NORTHERN CENTRAL HOSPITAL.

LECTURE III.¹

Delivered on March 4th.

TUMOURS OF THE SUPRAMARGINAL AND ANGULAR GYRI.

MR. PRESIDENT AND FELLOWS,—From the temporal lobe we may pass now to tumours of the supramarginal and angular gyri, convolutions of the inferior parietal lobe, which lie respectively round the posterior ends of the Sylvian fissure and the parallel sulcus so that the superior temporal convolution is connected at its posterior end with the contiguous parts of the supramarginal and angular gyri. What are the functions of the supramarginal and angular gyri? They are probably inexcitable to electrical stimuli in man, and according to Dr. David Ferrier² the angular gyrus is connected with vision and lesion of it causes temporary blindness of the opposite eye. In the case of tumours it would not be possible to exclude the structures which lie beneath the cortex and particularly the optic radiations, the fibres which run from the optic thalamus to the visual centres in the occipital cortex, and hemianopia may be caused by these fibres being involved.

In the first case the tumour was in the left supramarginal gyrus, the part of the parietal lobe which is posterior to the intraparietal sulcus and which lies round the posterior end of the fissure of Sylvius. In this case, under the care of Sir William Gowers, with a tumour on the left side which was subsequently removed by Sir Victor Horsley, there was for 13 months headache over the left occiput and the vertex, with tenderness above the left ear. There was no vomiting but marked optic neuritis was present. For 11 months there were several fits a day, with faintness, giddiness, and loss of consciousness but without convulsions. After the attack there was numbness of the right hand and the patient was dazed and could not speak properly. For five months he could not read or write. On admission there was weakness of the right arm and leg, with occasional twitching of the right fingers. He had momentary attacks of unconsciousness followed by difficulty of speaking and numbness of the right hand. Also he had word blindness, so that while he understood spoken commands and could name letters, words, and objects, he could not read except very simple sentences and could not make up words with letters. He made mistakes in writing. He had also right hemianesthesia with defective localisation, but his sense of position was good.

In the second case, under the care of Dr. Hughlings Jackson, a man, aged 27 years, had a large tumour—a glioma-sarcoma—in the left parietal region, where the growth came to the surface over an area of the size of a five-shilling piece. The growth was limited in front by the ascending parietal convolution and along the intraparietal sulcus the cortex of the brain was shrunken; behind, the angular gyrus was partially involved and by recent growth; below, the growth was bounded by the supramarginal gyrus which was not invaded and above by the superior parietal lobule, which was somewhat involved. It extended deeply inwards for about two-thirds of the distance to the median surface of the hemisphere. The onset was probably nine years ago, when the patient's speech suddenly became queer for two hours; his words were all right but his sentences were wrong, and then he had a fit, losing his senses and biting his tongue. He recovered speech on the next day. A year later he had a second attack which began with a peculiar feeling; he tried to

¹ Lectures I. and II. were published in THE LANCET of Feb. 9th (p. 343) and 23rd (p. 491), 1907, respectively.
² Croonian Lectures, 1890, p. 55.

speaking and could only say "Thank you," but could understand partially what was said to him. The whole attack lasted two hours and was not followed by paralysis. Another year later he had a third attack and lost his speech entirely, but could partially understand spoken words. There were no convulsions. Since then he had had several attacks, one a month, lasting a few minutes, losing speech but without convulsions. He did not lose power altogether of writing in the attacks. For three months he had had difficulty in reading aloud and some difficulty in writing.

On admission the patient's speech was slow but he understood spoken commands; he could pick out objects named to him and could name common objects shown to him but not the less common ones, though he recognised the name when it was mentioned. He understood what he read but he read slowly. He read badly aloud. In writing he could copy, but in writing from dictation he was very slow and incorrect, but he could write spontaneously fairly well, leaving out words here and there, and many words were crossed out. Smell, taste, and hearing were good. No optic neuritis was present. There was no loss of power or sensation, nor was there astereognosis. The reflexes were normal. The fields of vision were contracted. In hospital he had a fit beginning with loss of speech and with numbness and tingling and weakness in the right hand and foot; then he had "shimmering before his eyes and in waves." After the attack the field of the right eye was concentrically contracted. In most attacks he felt dizzy, lost his speech, or said wrong words, his eyes and head turned to the right, both legs and arms became stiff, and there was numbness of the right hand. He staggered to the right if he tried to walk. In the fits he had sometimes a sense of glaring light with the general weakness. Vomiting and retching occurred in the last three months. Later he had commencing optic neuritis, right disc = + 3.5, left = + 4.5, and the right side of the face was weaker than the left. The knee-jerks were both brisk. Plantar reflex: right indefinite, left flexor. He gradually became worse and died.

The main points in this case were the absence of severe vomiting and of headache till the last three months and of optic neuritis till the end, the attacks with loss of speech, the difficulty of reading with power to understand spoken words, the contraction of the right visual field, and the difficulty in writing, which was probably dependent on his difficulty of reading and was not an absolute agraphia. The part of the brain, lesions of which cause word blindness, is the angular gyrus, which in this case was not affected till later. It seems probable that the transient attacks were due to pressure and irritation of this gyrus rather than destruction of it, which would produce permanent word blindness. The concentric limitation of the field of the right eye would be due to the angular gyrus being involved and it bears out Dr. Ferrier's view that the whole field of the opposite eye is localised there. The absence of astereognosis does not support Dr. C. K. Mills's theory of its localisation in the superior parietal lobule.

In the two cases just described the tumours were situated in the parietal lobe of the left side; in the three following cases the tumour occupied the parietal lobe of the right side.

In a case under the care of Dr. H. H. Tooth there was a large tumour about one and three-quarter inches in diameter posterior to the intraparietal sulcus of the right side; there was no defect of speech and the fits were more like those from a tumour of the ascending parietal—viz., pain in the left arm going up to the face, with twitching of the left arm and leg. There were occasional incontinence of urine with weakness of the left arm and leg and probable loss of sensation over the whole left side and hemianopia, but as the patient was in a dull, stupid state from which he had to be roused to answer questions it was very difficult to test him.

The next case was that of a man, aged 37 years, under my care, who with no history of specific disease had two years before admission a general epileptic fit without any warning; then for five months he had unpleasant throbbing feelings and noises in his head, and he was treated by a medical man who said that his liver was out of order. A year later he began to have fits about once a week with pins and needles in the side of his left foot running up to the knee and then starting afresh in the left biceps, lasting for two minutes; there was a feeling of twitching in the left biceps like galvanic shocks but it did not move. Sometimes the feelings began in the arm. Two months before admission he had a general fit with unconsciousness but without any warning.

About nine months before admission he had an attack in which he became dazed and found that he had lost sight of his left half-fields, lasting for an hour and then passing off; he had four of these attacks in six months and they were not preceded by any visual aura, and two months before admission this left hemianopia became permanent. The sensations continued in the left foot but in one attack they began in the left side of the abdomen.

On admission the patient had no headache, no tenderness of the cranium, no optic neuritis, and no vomiting. There was no paralysis. The deep reflexes were brisk and equal and the superficial reflexes were normal. Sensation was normal. The sense of smell was defective on the right side. There was well-marked left hemianopia, so that he could not see anything to the left of the central point of vision in each eye. He left hospital on July 29th, 1904. On Dec. 7th of the same year he was readmitted. On every fifth or sixth day he had a curious sensation in the left side, beginning in the left leg, as if the leg were going to jump, though there was nothing to be seen, and this sensation passed upwards like a galvanic shock, with numb feeling in the left foot or arm; he felt as if he should fall. In the previous September he suddenly found that he had no feeling in the left hand and forearm; the anaesthesia lasted for ten minutes. There were no twitching, no pain, and no loss of power. Occasionally since then his fingers felt asleep and felt swollen. He had one general convulsive attack without any warning and with loss of consciousness. For ten days the left fingers, hand, and wrist felt weaker; also there was dragging of the left foot in walking. On readmission he had headache in the forehead, which was not severe. There was no vomiting. His memory was falling and he was languid and sleepy. His attention and intelligence were good. The hemianopia was getting worse. His speech was good. The left arm was weak, but could perform all movements. In regard to sensation, there was occasional numbness of the left fingers and hand, but no objective impairment. On Dec. 12th the upper edge of the right disc was blurred. On Feb. 10th, 1905, the whole of the right disc was blurred, + 3 dioptres; left, + 2 dioptres. There was headache later which was more severe. He had attacks of numbness in the left hand and in one attack there was weakness of the left leg. There was internal strabismus; the upward movement of both eyes was deficient; lateral movement of right eye to right not past median line; good on left. Sir Victor Horsley removed a double cyst from the right inferior parietal lobe posterior to the middle part of the ascending parietal convolution; the cyst was slowly shelled out, separating the cyst wall from the surrounding tissue. The tumour extended downwards and backwards and to a slight extent forwards.

The next case was that of a woman under my care who had a tumour measuring 2½ by 1½ by 1½ inches, involving the central white matter in the posterior half of the right hemisphere, and extending backwards to a point one inch from the occipital pole; it lay beneath the cortex of the supramarginal and angular gyri and extended across the white matter to the median surface where it formed a projection in the cortex of the quadrate lobule. Internally it involved the posterior part of the corpus callosum, the optic radiations, and the posterior quarter of an inch of the internal capsule. For five months before admission she had involuntary micturition; five weeks previously she had a general fit and after it she had paralysis of the left side. There was no definite optic neuritis till seven weeks before her death, and she had no headache or vomiting till after her admission to the hospital. Her mental condition was bad; she was in a torpid, drowsy condition, and refused food, and towards the end had frequent vomiting. The left pupil did not react to light and the right was sluggish. She had left hemiplegia with increase of the deep and diminution of the superficial reflexes, and extensor plantar reflex on the left side, loss of the sensation of pain and touch over the left half of the face, limbs, and trunk, and loss of the left half of the fields of vision for each eye (left hemianopia). Her speech was not affected.

The cases of tumour of the supramarginal and angular convolutions which I have just detailed to you are five in number, two being in the left hemisphere and three in the right. Taking first the general symptoms of tumour we notice at once either that these symptoms were absent or that they were developed very late in the course of the disease. Headache was present throughout in the first case and severe in the third case but in the other cases it was not severe and was absent till the end of the case. Vomiting did

not occur at all in three of the cases and only at the end in two cases. Optic neuritis was marked in the first case, it was absent in the third case, and in the other cases it was not observed till very late in the course of the disease. In all cases there were fits, either general convulsions without any warning, faints like petit mal, or Jacksonian attacks without loss of consciousness. These last fits were always preceded by a sensory aura, such as pain in the left arm followed by twitching. In one case besides general fits the patient had tingling in the left foot which spread up to the arm and he had the feeling as if the arm was twitching, but there was no actual movement. This sense of movement was probably due to irritation of the ascending parietal convolution. In one case hemiplegia occurred early in the case but in all the others there was only slight weakness of one side and this weakness occurred late either with normal reflexes or with the increase of the deep and diminution of the superficial on that side. Sensation in two cases was not permanently lost, although in both cases the patient had attacks beginning with a sensory aura, but in the other three cases there was hemianesthesia and in two cases hemianalgesia. Hemianopia of the fields on the side opposite to the tumour was present in every case except two, and in one of these the field of the opposite eye was concentrically contracted. The sense of smell was deficient on the same side as the tumour in two cases. The most important symptom was the affection of speech. In the three last cases when the tumour was on the right hemisphere speech was not affected; in the first two cases affecting the left hemisphere there was a definite amount of word blindness. In the first case the patient had dazed fits and could not speak properly, and subsequently could not read or write though he could name letters, words, and objects, and could understand spoken commands (i.e., auditory). In the second case the illness began with fits in which the patient's speech became queer, using wrong sentences, and before some fits losing his speech altogether. He could speak slowly, he understood spoken commands which he could hear, but had difficulty in reading and understanding written commands which he had to see. This patient had also fits accompanied by "shimmering waves and a glaring light."

In the foregoing account the fits, which begin with a sensory aura, are probably due to pressure on the ascending parietal convolution with consequent irritation of that part. Paralysis of motion and sensation does not occur unless the motor or sensory fibres of the corona radiata or internal capsule are pressed upon or involved by the tumour. The permanent hemianopia would probably be due to the optic radiations being invaded, while the concentric limitation observed in one eye would, according to Dr. Ferrier's experiments, be due to a lesion of the angular gyrus. The particular affection of speech called "word blindness," where the patient is unable to understand written commands which are brought to his mind through his organs of sight, is considered to be situated in the left angular gyrus, though in the first of these cases the tumour was removed from the supramarginal and probably compressed the angular gyrus. Therefore we may say that with tumours in the parietal lobe posterior to the ascending parietal convolution the general symptoms tend to be absent or to appear late in the disease; the fits are general or begin with a sensory aura; paralysis of the side opposite to the tumour with the accompanying alteration of the reflexes is absent, slight, or occurs late, unless the tumour extends deeply, as in the last case, and involves the internal capsule; hemianesthesia and hemianopia on the opposite side occur frequently and if they are permanent it would show that the sensory fibres and the optic radiations were destroyed. If the tumour be in the left parietal region word blindness, either transient or permanent, is present.

TUMOURS OF THE PITUITARY BODY.

The tumours which I propose to bring next to your notice are the tumours of the pituitary body. This body is situated in the centre of the base of the brain in the middle line and it rests in the hollow of the sella turcica just behind the chiasma the optic nerves. From its proximity to the chiasma the optic fibres, which come from the inner or nasal half of each retina, are liable to be pressed upon by a tumour growing in the pituitary body and thus to produce blindness of the inner half of each retina. Now, the rays of light which impinge on the nasal or inner half of each retina come from the outer or temporal fields of each eye; hence in tumours of

the pituitary body patients suffer from the loss of vision for the outer half of the field of vision of each eye, or bi-temporal hemianopia. Further, there is a peculiar disease, which was first described by Dr. Pierre Marie of Paris, and which is characterised among other symptoms by enlargement of the extremities, the hands, feet, nose, and chin, and is called acromegaly. In a certain number of these cases enlargement of the pituitary body has been found, and in these cases bi-temporal hemianopia has been present. The exact relation between the pituitary body and acromegaly is not quite certain, as every case of tumour of the pituitary body does not show signs of acromegaly.

The first case of tumour of the pituitary body, which was under my care seven years ago, was that of a woman, aged about 29 years, who five years previously had a severe mental shock. For four years she had severe headache and vomiting, and three years ago she had diplopia, which lasted only for a month. At this time she felt very listless and her skin felt to be too thick. About six months later she had pain in her right eye. She ceased to menstruate, for which she consulted Dr. A. E. Giles who asked me to see the patient. She got thin, but her hands and feet were noticed to be large, and a year before I saw her she had curious attacks of feeling strange, with a horrible feeling of dryness in the mouth followed by a glow all over her lasting for one minute but without loss of consciousness; also she had attacks of feeling faint and attacks of vomiting several times a week. There was slight headache over the right eye. When I saw her she had double optic neuritis, but there was no limitation of the fields of vision. She had paralysis of some of the ocular movements; with the right eye she could not look upwards and she had some diplopia on looking in all directions. The right pupil was larger than the left and it did not react to light though it did dilate when shaded. Besides these symptoms the face was noticed to be unsymmetrical; also it was observed that the extremities—viz., the feet, the hands, and the nose—had grown larger than they should be. She later developed bi-temporal hemianopia. A month or two later Sir Victor Horsley removed some bone in the right temporal fossa to give vent to the increased intracranial pressure and it was noticed at the operation that the bone was of a remarkable blue colour and had a thin fibrous appearance like papier-mâché and cutting it with bone forceps produced no sound. Her headache and vomiting were much relieved by the operation. She died about four years later and a tumour was found in the pituitary body compressing the base of the brain.

The next case was that of a man under my care, aged 36 years, who had for two years complained of pain in the frontal or occipital regions, failing eyesight which was blurred and worse for the last three months, vomiting which occurred daily a week before his admission, and general weakness. He had also occasional attacks of giddiness. Mentally his memory had become very bad and he had been lethargic and drowsy with definite delusions. On admission the sense of smell was not affected; the optic discs were both pale with evidence of old neuritis. He had bi-temporal hemianopia—i.e., loss of the outer half of the field of vision for each eye. The right pupil was larger than the left and did not react to light; the left pupil reacted when light was directed on to it from the inner or nasal side but it did not react when light was directed on to it from the outer or temporal side, thus showing that the inner half of the left retina was insensitive to light. This symptom is called the hemiopic pupil reaction and was first called attention to by Willbrand, and it shows that there is a lesion which is affecting the fibres in the optic nerve or tract somewhere between the retina and the centre for the con- traction of the pupils in the corpora quadrigemina, and in this case it would show that besides completely abolishing the pupil fibres in the right optic nerve the lesion was pressing especially on the fibres in the chiasma which come from the inner half of the left retina. The external ocular movements were normal. The lower part of the right side of the face showed defective movement, but otherwise there were no paralysis and no alteration of the reflexes. The hands were noted to be large but it was doubtful whether he had true acromegaly. A diagnosis of tumour of the pituitary body was made and Sir Victor Horsley operated from the right temporal fossa in two stages and reached the pituitary body which was occupied by a cystic tumour which was scraped out and drained. With regard to this operation I would say that Sir Victor Horsley has now operated on ten cases of tumour of the pituitary body.

The third case was that of a man, aged 29 years, under the care of Sir William Gowers, who for seven years had his sight affected and which was getting worse for three and a half years when he stated that he began not to see properly with one part of each eye. He was dull, drowsy, and sleepy; his memory was bad and at times he was restless and had delusions. He complained of diminution of sexual power and for six months he stooped and walked slowly. His smell was deficient, so that he could perceive, but not recognise, odours, but his taste was good. He had bilateral hemianopia with diminished vision, R.V. = $\frac{1}{5}$. On the right side the vertical dividing line passed through the fixation point, a condition which is unusual in cases of hemianopia from a lesion of the occipital cortex, and on the left side there was considerable contraction of the nasal fields, with loss of vision at the fixation point. The optic discs were pale with primary atrophy. The pupils showed the hemiplegic reaction—i.e., they reacted when light was thrown into them from the inner or nasal fields but scarcely at all when it came from the outer or temporal fields. The ocular movements were good, without nystagmus. There was fine tremor in both hands when they were held in front of him. There was no enlargement of the hands. At the operation a tumour of the size of a walnut was removed from the pituitary body by Sir V. Horsley.

The tumours which we have been considering are those that come within the powers of the surgeon to remove if their localisation can be sufficiently accurately determined and I now propose to bring to your notice some tumours of the basal ganglia which are presumably impossible to remove.

TUMOURS OF THE OPTIC THALAMUS.

I will take first tumours of the optic thalamus. This is a part of the brain of which the function is less known than that of other parts such as the cortex, but different symptoms have been described by various writers and these symptoms of lesions of the posterior part of the optic thalamus have been in the last year well put together by Déjerine and Roussy.¹ The chief symptoms are that voluntary movements are not much affected unless the internal capsule be involved, but involuntary movements and ataxia of the opposite limbs occur; the tendon or deep reflexes are slightly increased or are normal; the superficial reflexes are normal or absent, but the extensor plantar reflex (Babinski's sign) was not obtained in spite of the pyramidal degeneration which was present in some of the three cases on which the work is founded. Sensation was affected both objectively and subjectively; in the former all forms of sensation are involved but not absolutely and the loss is more marked at the periphery. Muscular sense and stereognosis, or the recognition of objects by the touch, are, however, completely lost. Subjectively there are severe pains in the limbs and hyperæsthesia, which is sometimes so severe as to prevent the use of the limb. Hemianopia occurs if the postero-inferior part of the thalamus be involved. The other special senses are not affected.

I have notes of three cases which were respectively under the care of Dr. H. Charlton Bastian, Sir William Gowers, and Dr. Ferrier. The first case was in the right optic thalamus but it also extended down into the right crus cerebri, and there were headache and vomiting and double optic neuritis, together with gradual weakness of the left arm, leg, and face, with some increase of the deep reflexes on that side. At first sensation was not affected but later there was left hemianæsthesia but apparently no hemianopia. The patient had several curious fits lasting half an hour and consisting of tonic rigidity of the left arm and leg. Mentally his memory was good but he was always falling asleep. Later he became comatose and had fits affecting both sides.

In the case under Dr. Ferrier the tumour occupied the whole of the left thalamus, especially its posterior part, and projected into the posterior part of the lateral ventricle, and also extended across the middle line to the right thalamus and back to the corpora quadrigemina. The patient was fatuous and suspicious and had numerous general fits, followed by hallucinations. There was no motor or sensory affection, but later there was right hemianopia.

In the case under Sir William Gowers the tumour was very large and involved the left thalamus and left internal capsule, spreading across to the right thalamus and down into the pons. The patient, a girl, aged 15 years, had fainting unconscious fits, with weakness and then anæsthesia

of the right hand and later of the right leg. On admission there was slight right hemiplegia with right hemianæsthesia and right hemianopia with some ataxia of the right hand, a symptom of lesions about the optic thalamus which was described some years ago by Sir William Gowers, and increase of the deep reflexes and diminution of the superficial with extensor plantar reflex. In addition there was left ptosis but the ocular movements were normal.

The internal capsule lies so close to the optic thalamus that it is very difficult in the case of a tumour not to have the internal capsule involved or pressed upon, and consequently in two out of the three cases described above there were hemiplegia and hemianæsthesia, and in one case hemianopia. In one of the cases there were no hemiplegia and no hemianæsthesia and only hemianopia coming on later, and in this case it would be very difficult to make a diagnosis of optic thalamus as the symptoms might be caused by a tumour of the parietal or the occipital lobe.

A history therefore of a slow progressive hemiplegia with hemianæsthesia and hemianopia all on the same side, with fits of a general nature but without any localising symptoms such as numbness in one hand followed by epileptiform attacks, as we found to exist in tumours of the parietal lobe, would make a diagnosis of a tumour about the optic thalamus and the posterior limb of the internal capsule probable. In both the cases where the internal capsule was involved the plantar reflexes were extensor in character and not flexor as described by Déjerine and Roussy, and in none of the cases were there severe pains in the limbs. In one case ataxia of the paralysed side was observed.

While speaking of tumours of the optic thalamus I would refer to some cases occurring at the National Hospital which were attended by marked tremor and incoördination of the limbs and which have been found by Dr. Gordon Holmes² to be due to tumours of the part lying beneath or ventrally to the optic thalamus known as the red nucleus which receives the superior peduncle of the cerebellum.

TUMOURS OF THE CORPORA QUADRIGEMINA.

The first case is that of a man, aged 42 years, under Dr. Ferrier's care. Six months previously he had headaches, chiefly occipito-vertex, which continued for two months; he had had none since. There was giddiness, during which he felt forced to the left. There was a tendency to fall backwards or to step back, and he staggered, always deviating to the left. For one to two years the sight was getting slowly worse. The hearing was poor, with tinnitus. For three months he had had diplopia. There were no vomiting, mental changes, or fits, but his memory was poor. He was apathetic. As regards the vision the left eye was better than the right; well-marked recent optic neuritis was present. There was great impairment of the upward movement of the eyes. There was slight divergence of the visual axes, but the lateral movements were good. Downward movement of the right eye was defective. Convergence of the right eye was poor. The pupils were small and inactive to light and accommodation. In walking he deviated to the left, keeping his right shoulder in front and his head to the right. The deep reflexes were normal; the abdominal reflex was diminished on the left side. The plantar reflex was flexor. There was marked tremor in the left hand, like that of paralysis agitans. A tumour, a glioma, was found extending the whole length of the mid-brain from the posterior commissure to the valve of Vieussens, and the tumour involved both the anterior and the posterior corpora quadrigemina of the right side, and a process of growth was seen between the red nuclei—the termination of the superior cerebellar peduncles.

The next was a case under the care of Dr. T. Buzzard, in which the patient, a girl, aged six years, had two tuberculous growths on the right side, one in the anterior and to a less degree in the posterior corpora quadrigemina, and the other, a ventral tumour, occupying the right nucleus ruber. The onset was gradual and for five weeks the right eye was closed. For two weeks she had tremor of the left arm spreading to the right arm, and for ten days vomiting with drowsiness. She had headache for four days; her gait was much affected and she tended to fall to the left. On admission the optic discs were engorged but the margins were clear. The pupils were unequal; the right was pear-shaped and larger than the left; there were no reaction to light and doubtful reaction to accommodation. There was marked paralysis of

¹ Le Syndrome Thalamique, Revue Neurologique, June 30th, 1906.

² Brain, 1904, p. 257.

the muscles of both eyes, especially of both third nerves, so that there were ptosis on both sides and no movements of the eyes except outwards and downwards with wheel motion (?superior oblique), and slight power of convergence on the left side. The facial muscles were weak on both sides; the tongue was protruded to the left. There was general stiffness of all the limb muscles; the head lay towards the left shoulder; the left limbs were weak, with coarse irregular tremor of both arms at all joints but more in the left than the right. The tremor occurred when the arms were at rest but not during sleep, and it was increased on volitional movement. When the patient stood up there was tremor in the left leg and she fell to the left in walking.

A case under the care of Dr. Ferrier, a man, aged 53 years, had left-sided headache and two months before admission he suddenly fell down, was dazed and giddy, and the attack was followed by diplopia with staggering to the right. Another attack occurred two weeks later. On admission he had headache and vomiting but no optic neuritis. His speech was indistinct; he was drowsy but intelligent; he had diplopia. He had marked ocular symptoms, double ptosis, and marked paralysis of the lateral movements of the left eye with paralysis of the right internal rectus; the upward movement of the left eye was very feeble. The pupils were small, equal, and reacted extremely slowly to light. There were slight right facial weakness and progressive paresis of the right arm and leg. The left external pterygoid, temporal, and masseter were weak. There were anaesthesia and relative analgesia of the right face, arm, and leg. The right knee-jerk was absent and the left was feeble. The plantar reflex was flexor on both sides. A tumour (sarcoma) was found in the anterior corpora quadrigemina measuring one and a quarter by one and a half inches, not involving the posterior corpora quadrigemina, the crura, or the optic thalamus. The aqueduct of Sylvius was pressed upon.

According to Dr. Ferrier's observation and experiments on the corpora quadrigemina it would appear that these bodies are connected with the movements of the eyes and pupils, with vision, and with equilibration. In the three cases which I have brought before you in all of them there was marked paralysis of the movements of the eyes and especially of upward movement, and also absence of reaction of the pupils to light and in two cases to accommodation. As the corpora quadrigemina lie just above the nuclei of the third nerves, it is exceedingly difficult to say how much of this ocular paralysis is due to direct involvement of the corpora quadrigemina by the tumour and how much to the indirect pressure on the nuclei of the third nerves. Another symptom which is important in view of the association of these bodies with equilibration is that in three cases the patients are described as staggering towards the side which was opposite to the lesion. Therefore in a case which presents the general symptoms of tumour, marked paralysis of the ocular movements with fixation of the pupils and staggering to one side is in favour of a tumour of the corpora quadrigemina. These cases are often difficult to diagnose and we must remember that paralysis of the ocular muscles and fixed pupils are met with in cases of locomotor ataxia, but in these cases while there would probably be other symptoms of locomotor ataxy, they would not present the general symptoms of a tumour.

TUMOURS OF THE CEREBELLUM.

I would remind you that the cerebellum consists of two lateral hemispheres joined by a median portion called the vermiciform process. We have therefore to consider tumours growing outside the cerebellum and compressing it and tumours growing within the cerebellum or, in other words: (1) extra-cerebellar tumours, and (2) intra-cerebellar tumours, divided into (a) tumours of the lateral hemisphere or lobe and (b) tumours of the vermiciform process. We have, as in tumours of other parts of the brain, the three general symptoms, headache, vomiting, and double optic neuritis; and we have, further, the following localising symptoms: vertigo, pressure on cranial nerves (auditory, facial, trigeminal, sixth nerve), motor symptoms (on the same side as the lesion), such as weak conjugate movements of the eyes, nystagmus, paresis of the limbs and of the trunk muscles, loss of tone in the muscles, ataxy of movements, tremor, staggering gait, alteration of the deep reflexes, with normal superficial reflexes, and peculiar fits. Time will not permit me to mention the experimental work of Ferrier, Luciani, Risien Russell, and of others, or of the clinical work of

Hughlings Jackson, Gowers, Alexander Bruce, Mills, Allen Starr, and others.

I have already enumerated above a general list of the symptoms of cerebellar tumours, and it will now be necessary to point out the different way in which these symptoms show themselves in extra-cerebellar and intra-cerebellar tumours. For this purpose I shall avail myself of the results obtained by Dr. Grainger Stewart and Dr. Gordon Holmes¹ who have written a paper based on a series of 40 cases of tumour of the cerebellum observed at the National Hospital, Queen-square. Of these cases, in 22 the diagnosis was confirmed by operation or by necropsy.

Taking, first, the extra-cerebellar tumours, we find that the majority of them grow from the flocculus or the auditory nerve in the anterior part of the posterior fossa. They are wedged in the angle between the cerebellum and the pons close up to the petrous part of the temporal bone and compress these structures without actually involving them. Occasionally we meet with cases in which the tumour lies more posteriorly in the cerebellar fossa of the posterior fossa and would compress the lateral lobe of the cerebellum and would give probably the same symptoms as an intra-medullary tumour of the lateral lobe. With this proviso I will refer to these tumours in the anterior part of the posterior fossa as extra-cerebellar growths and those within the lateral lobe of one side as intra-cerebellar tumours.

In both extra-cerebellar and intra-cerebellar growths the headache is severe, vomiting is nearly always present, and optic neuritis is, perhaps, more early in its appearance in intra- than in extra-medullary tumours. Of the localising symptoms, vertigo or giddiness is a frequent symptom in both forms of tumour. True vertigo is either a feeling that the patient has that objects are revolving round him or a feeling that he himself is revolving round his axis. Now, according to the two authors quoted above, in both forms of tumour the patient in the vertigo thinks that objects are going in the direction away from the side of his lesion; in other words, with a left-sided tumour the objects would seem to go from the patient's left to his right. With regard to the patient himself with intra-cerebellar tumours he seems to turn in the same way as the objects—i.e., from left to right—whereas in extra-cerebellar cases he seems to turn the opposite way—i.e., from right to left. Taking first extra-cerebellar tumours we find that compression of the cranial nerves, and especially of the auditory and facial nerves, is a very common symptom, as these tumours grow close to the internal auditory meatus where these nerves enter the cranial cavity, and as a result we get loss of hearing to sounds heard through the air, as well as those conducted by bone, also tinnitus, buzzing or switching noises; facial paralysis involving all parts of the face; occasionally the fifth nerve, the trigeminal, is pressed upon, and especially the sensory part, causing numbness, tingling, or loss of sensation of the face on the same side as the tumour; also in many cases paralysis of the sixth nerve with weakness of the external rectus; rarely the ninth, tenth, and twelfth nerves. This compression of the cranial nerves does not occur in intra-cerebellar tumours. Motor symptoms occur on the same side as the lesion. This shows itself in the conjugate movements of the eyes, so that there is difficulty in turning both eyes towards the side of the lesion, and this is attended by nystagmus, slow jerking movements when the patient looks towards the side of the lesion. This occurs in both forms of tumour, perhaps more in extra-cerebellar. In the limbs on the same side as the lesion in intra-cerebellar lesions there is diminished power, and in a few cases it was observed that the muscles of the spinal column, especially the erector spinae, of the same side were weak. This paresis is more common in intra-cerebellar cases. Associated with the hemiparesis there is loss of tone, so that the muscles of the limbs on the same side as the lesion are flaccid and flail-like, and the two authors I have quoted point out that though in locomotor ataxy this flaccid condition is associated with absent knee jerk in cerebellar tumour it is often combined with an increase of this reflex. They also mention a condition which is important—viz., that if a normal person executes a movement against a resistance which is suddenly removed he is able to prevent the movement being carried on by bringing into action the antagonist muscles, but in cerebellar tumours this power appears to be lost. Also ataxy

is present in the paretic limbs which is not increased when the patient closes his eyes, showing that its origin is central and is not due to peripheral sensory changes as in locomotor ataxy.

Associated with incoördination is the condition pointed out by Babinski in the paretic limbs of the same side—viz., that the patient cannot rapidly pronate and supinate the forearm owing to a defective coördination of the muscles. I have myself seen this symptom in several cases of cerebellar tumour, but according to Stewart and Holmes it cannot be looked upon as pathognomonic of cerebellar disease. Both ataxy and this last symptom occur equally in the two forms of tumour.

According to the same two authors in extra-cerebellar tumours there are irregular tremors in both arms when they are horizontally extended, while in intra-cerebellar tumours they are absent. The peculiar reeling, staggering gait has been known for some time and it has been described especially by Dr. Hughlings Jackson. It is best likened to that of a person trying to walk on a rolling ship at sea, but with a tendency to go to one side more than the other. The difficulty has always been to determine to which way the patient tends to fall. According to the two authors mentioned above the patient tends to stagger and to deviate towards the side of the lesion and he would thus walk in a circle, but he knows his weakness and tries to counteract it by bringing forwards the shoulder on the same side as the lesion. Another way of testing which side is affected is to make the patient stand on one leg and then on the other and it will be found that he is more unsteady on the leg of the same side as the lesion. This walk occurs in both forms of tumour. In tumours affecting the vermis in the middle of the cerebellum the reeling is more uniform and the patients tend to fall backwards or forwards.

The condition of the reflexes is one of much importance and especially the knee-jerk. According to the same authors in extra-cerebellar tumours the knee-jerk is not altered, while in intra-cerebellar tumours of one side the knee-jerk on that side is, if anything, diminished, but this is very uncertain, and from the cases which I have seen I should not be disposed to think that any definite conclusion can be drawn. The superficial reflexes are not altered in intra-cerebellar tumours and I have myself never seen the extensor plantar reflex in pure cerebellar cases.

It must, however, be remembered that, in extreme pressure from an extra-cerebellar tumour on the pyramidal tract in the pons, paresis may occur in the limbs on the opposite side to the lesion, due to decussation of the pyramidal tract below, but when this is the case there will be some rigidity with increase of the knee-jerk, diminution of the superficial reflexes, and the extensor plantar reflex in the opposite limb.

Dr. Hughlings Jackson has described peculiar fits occurring in tumours of the vermis, with retraction of the head and arching of the back. I have in two cases at the Great Northern Central Hospital⁶ seen this arching of the back with tonic contraction of the erector spinae, but one of these cases was a hydatid in the posterior cornu of the right ventricle and both muscles were contracted, and the other was a case of chronic hydrocephalus in an adult and only the right erector spinae was contracted; the contracture might have been caused by pressure on the vermis of the cerebellum.

The diagnosis of cerebellar tumours from cerebral is made by a comparison of the symptoms given above with those which were found to exist in tumours of the cerebrum. The absence of mental symptoms, of sphincter troubles (except at the end of the disease), and of epileptiform attacks, the presence of a reeling gait associated with deviation, say, to the left, with weakness of movements of the eyes to the left and paresis of the left limbs without alteration of the reflexes, would be in favour of an intra-cerebellar tumour of the left lateral lobe; while deafness and facial paralysis of the left side with conjugate weakness of the eyes and paresis of the limbs of the left side, and with weakness and rigidity of the right limbs, together with increased knee-jerk and extensor plantar reflex, would be due to an extra-cerebellar tumour of the left side.

Tumour of the pons at its lower part might be taken for cerebellar cases but in a typical case due to a lesion in the left half of the pons there would be complete paralysis of the left face, and perhaps left deafness, the eyes would be conjugately deviated to the right, and there would be spastic

paralysis of the right arm and leg with increase of the right deep reflexes and extensor plantar reflex, and the paralysis would come on early and would not be preceded by a reeling gait.

There is one point with regard to the optic neuritis on which I should wish to say a word. Without counting the 40 cases of cerebellar disease described by Stewart and Holmes, who state that in the majority of the cases, the swelling of the papilla was greater on the side of the growth, I find that out of 50 cases, which I have described to you, in 19 the neuritis was more intense in the eye on the same side as the lesion, in 11 cases more in the opposite eye, in 13 it was equal on the two sides or there was no note to say that there was any difference, and in seven cases there was no neuritis.

In conclusion, I would say that I have endeavoured to bring before you the symptoms which were associated with tumours situated in different parts of the brain, and if these symptoms are present it is possible in many cases to make a correct diagnosis; in some cases where there are no symptoms or where the symptoms are misleading it is not possible and I would refer you to an interesting paper by my colleague, Dr. James S. Collier,⁷ who points out the false localising signs of intracranial tumours which may mislead the unwary—aye, and the wary too. It only remains for me to thank you for the kind attention which you have given.

ABSTRACT OF

The Morison Lectures

ON

INSANITY, WITH SPECIAL REFERENCE TO PROGNOSIS.

Delivered before the Royal College of Physicians of Edinburgh on Jan. 28th and 30th and Feb. 1st, 1907,

By A. R. URQUHART, M.D. ABERD.,
F.R.C.P. EDIN.

PHYSICIAN-SUPERINTENDENT, JAMES MURRAY'S ROYAL ASYLUM,
PERTH.

LECTURE III.¹

Delivered on Feb. 1st.

HAVING reviewed the clinical experience of 25 years from a statistical point of view, I shall now proceed to consider certain correlations between somatic and mental phenomena. There is no doubt just at present some disparagement of psychology in these studies and a sceptical attitude towards the assumed occurrence of a mental disorder without an operative physical cause, yet I cannot range myself with the opponents of psychology. For instance, by his researches into the phenomena of fatigue, Kraepelin has explained what was formerly obscure and improved the methods of education throughout Germany. Mental fatigue and bodily fatigue exercise the same effects upon the brain and it is a mistake to suppose that by altering the kind of fatigue reparative processes will be encouraged thereby. Italian observers have demonstrated the toxic nature of fatigue in the lower animals and we can precisely understand the process.

The age and health of the parents at the time of conception of offspring are of importance in the evolution of the race. I have recorded several instances of paternal drunkenness in this connexion, but the mere accident of one act of drunkenness is relatively unimportant compared with the habitual condition of the persons noted. Nor have I been able to discover any relation between the use of midwifery forceps and the individuals who have come under my care.

What is of real importance in the study of neuropathic children is the immediate ancestry, the environment, and the education which condition them. Dr. Dewey of Chicago has investigated the early life conditions in 200 sane and 200 insane persons. This comparative method elicits a series of facts which tend to confirm the observations which I have submitted. Briefly, whatever tended to eugenics

¹ Brain, 1905, p. 450.

² Lectures I. and II. were published in THE LANCET of March 2nd (p. 572) and 9th, 1907 (p. 645), respectively. The lectures were illustrated by statistical tables, charts, and clinical observations.

⁶ Brain, 1906, p. 227.

found expression in the sane in a higher degree than in the insane. For instance, excessive use of alcohol, of tobacco, of tea, and of coffee appears more frequently in the insane families; tuberculosis, insanity, and malarial environment follow the same rule. Neglect and poverty, lack of home discipline, and defective schooling were all more apparent among the insane. In short, a neuropathic heredity was continued in a neuropathic environment and issued in a neuropathic generation.

The evolution of character, ability, temperament, and success has not been studied with that care which the subject demands. It is not sufficient to write around the great names. We know that the race tends to average abilities, with some slight advantage to the families of exceptionally able, *well-balanced*, intellectual parents. It is the kind of mistake to which I have already referred that exclusively considers the exceptional, the bizarre, and the extremes. For the determination of the probabilities of inheritance of any character, physical or mental, within normal limits or the possibilities of disease a study of the general population is absolutely necessary. The successes and the failures must be considered in detail. Professor Karl Pearson has found that the intensity of correlation between "want of mental balance" in parents and insanity in children is from 0.25 to 0.30, probably the same as exists in regard to other characters—e.g., stature, colour of eyes, and so on—thus showing, as might be expected, that somatic conditions are paramount in the first instance; however environment may possibly influence the organism in its growth and development. I plead that Professor Karl Pearson will have the support of the College in his endeavour to collect sufficient data for the further elucidation of this question, in the firm belief that the results will lead to a better understanding of the national requirements towards the attainment of health and efficiency.

As sleeplessness is the most invariable prodromal symptom of insanity, so it is of the greatest importance in the course of the malady, whether from the view of treatment or prognosis. The high pressure of the blood interfering with repose and nutrition is the chief disturbing factor. The whole endeavour of treatment must be bent towards the restoration of sleep not so much by the crude effects of narcotics as by the wider application of medical skill. It is not my purpose to touch upon treatment or nursing, nor is it necessary to insist on the importance of this point. The management of the insane at night is quite as important as their management by day and their conduct at night is just as indicative of their future as their conduct by day. The return of sleep is a sign of recovery or failure to recover—a good sign if improvement is concurrent in other directions, a bad sign relatively if there is no, or but partial, concurrence. For insomnia is not a symptom of chronic insanity. Excepting a few cases of chronic mania, a few of circular insanity in the excited phase, and especially of that class in which hallucinations are prominent or the *cenæsthesia* is greatly perverted, the old cases sleep soundly and are aroused with difficulty. This restoration of sleep bears a close resemblance to the increase of body weight. If the nutritive processes become active and there is a concurrence of other favourable signs the outlook is hopeful, but degeneration may go hand in hand with an unhealthy pallor and an undesirable, flabby corpulency accompanying permanent feebleness of mind.

When the somatic failure is general it is evident to the most casual observer. The chronic degraded patients of one asylum closely resemble those of their class in any other asylum. We cannot neglect the facial appearance of the patient in discussing the question of prognosis. It is characteristic of degradation, if degradation has declared itself. Apart from the emotional expression of the prevailing mental tone there is an immobile, listless, preoccupied appearance which augurs badly for the future. The nervous system is out of gear and the enfeebled muscles indicate that failure. The complexion is pallid and the skin shares in the general inefficiency. The eyes are relaxed and their mobility is restricted. Pigmentation of the skin is of evil omen, and if it is systematically picked by the patient one can hardly look for recovery. The morbid condition of the skin in insanity has not been sufficiently investigated as yet. The development of nervous system and skin from the point of view of embryology may in some measure elucidate these complications. In any case the extremes of harsh dryness in certain forms of melancholia and copious perspirations in certain forms of mania are commonly recognised. Also

the greasy offensive appearance in degraded cases. Perhaps the most important cutaneous symptom from the point of view of prognosis is the pigmentation which so frequently occurs and which must be considered as indicative of a progressive and intractable disorder when it is unmistakable and long continued. The appendages of the skin are also affected. The state of the hair is a valuable index to the general condition.

The general nutrition, perhaps, is the most certain index of the progress of a case, as has been well brought out by the study of body-weight in recoveries and removals. In asylum life the periodical and exact weighing of patients is a routine practice generally adopted and generally trusted to indicate the variations in somatic conditions which are so important in the adoption of remedial measures suitable for each particular case; also as indicative of the earliest warnings of complications, such as tuberculosis. A restoration of lost body-weight, like a restoration of diminished secretions, is almost invariably one of the first signs of returning health.

The muscular system presents very many problems of interest apart from the pareses and paralyses of pathological insanity. The fumbling fingers of a general paralytic fail in muscular energy, in coördination, and in the guiding direction of the higher cortical centres. In lesser degrees the finer adjustments of intention and action are discernible in ordinary insanity, and as the degradation deepens so the inability becomes declared. The somatic failure is then positive. But as a general rule it may be stated that the deeper the mental degradation the more obvious are the reflex defects, whether motor or mental. All cases displaying rhythmic, monotonous movements are to be regarded as most seriously damaged. In some cases these movements, apart from idiocy, have a gross pathological basis. The morbid condition of bones in the insane has long been recognised and I believe that the anæmic failure of the chronic insane is part and parcel of the osseous defect. I shall not venture to discuss questions of craniology, in reference to which palatal deformities are of importance in determining a neuropathic heredity in many cases where information is given reluctantly. A few words may be permitted in reference to oral sepsis and a common symptom of general paralysis—a persistent grinding of the teeth.

The gait of insane patients is characteristic: the bent, stiff neck, the downcast eyes, the untidy dress, the careless slouching walk, are all in various degrees indicative of somatic and mental degradation. Extraordinary attitudes impress one unfavourably. Often these are assumed by adolescents who may recover, but my experience is that they are symptomatic of relapse sooner or later. Alterations in handwriting and tricks of voice or speech indicate the inter-action of mind and body in many important directions. Vain and purposeless repetitions of phrases in the letters of a person not appreciably insane are often evidence of chronic alcoholism and specially, I believe, of cocaineism. In the case of a person tending towards chronic insanity such repetitions are a mark of incurability. The corresponding phrase of speech is not less ominous; still there is a lower grade—*echolalia*, in which there is a repetition of words heard by the patient and immediately reproduced, and lower still in the scale is *verbigeration*, in which new words are invented.

To resume, then, these various conditions of the organism betray each in its own relations, the generalised nature of the insanity, the generalised defect and disorder in which the mental symptoms originate, and upon which they depend. Within the compass of these brief lectures it is impossible to discuss all the somatic conditions. I rather endeavour to indicate the trend of experience, and prefer to reserve the consideration of highly specialised subjects of importance, such as the work of Flechsig relative to the association fibres of the brain demands.

I now, therefore, attempt to correlate somatic disorders with the mental phenomena of insanity. It is generally recognised that prognosis will vary with the incidence of these disorders and diseases. If bodily health can be re-established there is hope of mental improvement and recovery. For instance, if there is no possibility of restoring a damaged cardio-vascular system the outlook is gloomy. Prognosis therefore must await the determination of these events. Of course, those with somatic stigmata generally tend to marked mental degeneration. It is necessary to read for hæmopoietic disorders, *anæmia*. The sary to read for the blood, discoverable by modern methods, can, of course, find no place in old records. In the

cardio-vascular group it is important to note the depression and fears which are exaggerations of the usual features of these maladies. Gastro-intestinal cases are similarly affected. The great excess of the female sex under the heading of generative disorders is in accordance with general experience. I have not been able to corroborate certain American observations which record extraordinarily voluminous morbid details in the sphere of gynaecology. There can be no doubt that the urine and vaginal discharges of the insane are highly toxic, but the vast array of surgical necessities alluded to is not within my experience, either by the bedside or in the post-mortem room.

The common concomitant of generative disorder is the irregularity or suppression of the catamenia. It is usually said that menstrual periods are accompanied by exacerbation of insanity. That is by no means the rule according to my observations. No doubt the return of catamenia is a favourable indication and we have had several such cases after the exhibition of ergoapial where other drugs had failed. I might also record a case of recovery in which the catamenia continued suppressed and were restored by the introduction of a stem pessary at home. Quite exceptionally, I have had good results from the use of ovarian extract after ovariectomy, but can present no case under asylum treatment in which that preparation altered the mental condition. It is our routine practice to record daily on calendars the excitement or depression noticeable in individual patients. These calendars also show the days of menstruation. I have condensed these observations for years together, and on examination of the results find that it is quite exceptional to correlate the catamenia with the exacerbations of insanity; occasionally this is discovered in mania but never in melancholia, so far as my observations go. What is of much more importance are the toxic conditions of these tracts—whether puerperal or not.

My aim has been to direct attention to somatic disorders and to correlate those with insanity under two broad divisions—ordinary and pathological. Yet it is necessary to say something in general terms. For instance, the primary fact of consciousness has a relation to prognosis; if it is lost for any considerable space of time it is a measure of mental degradation indicating incorrigible defect. Mere confusion is not at all a hopeless condition, but delirium is of the gravest import. I have not found that perversions of identity are so incurable as was formerly supposed; but as a general rule it may be stated that perversions relative to self are much less intractable than those relative to others. Did time permit, these opinions could be supported by clinical illustrations, but I must pass to the sphere of sensation. The general catathenia is of importance in this connexion. It is a common measure of convalescence to observe carefully the mental attitude relative to fatigue. A loss of the sense of fatigue, an abolition of sensation in regard to fatigue, denotes an uninterrupted course of mental disorder; on the contrary, when the patient begins to complain of fatigue and pain and discomfort the complaint is welcomed as the first sign of improvement.

The sensations colour the delusions, and in that respect the study of Table XVI. is interesting. The genesis of delusions from the painful sensations of gastro-intestinal disease is readily understood—it is easy to pass from the feelings of gastritis to the feelings of poisoning. In fact, I would venture on the generalisation that perverted sensations determine the tone of the delusions and the general mental condition. It is unthinkable that the depressing nature of abdominal disease, altogether apart from insanity, should issue in grandiose ideas or pleasurable excitement. It would seem that hallucinations can be an affair of auto-suggestion in some cases. The measure of degradation may be ascertained by observation of the power of attention and memory, yet these may be acute and the condition of the patient may be hopeless as regards recovery. It is commonly supposed that an unimpaired memory is an indication of sanity, yet the idiot savant may have a memory of extraordinary tenacity. The perversion of intellect may be complete and both attention and memory perfectly unimpaired.

In point of time, we have already seen that recent cases are most favourable in expectation of recovery and that cyclic variations are common; also that a sudden onset and a sudden recovery almost inevitably mean neuropathic inheritance and recurrence sooner or later. A settled periodicity is bad, yet if there are no remissions tending to recovery the outlook is not less gloomy. The best sign in this respect is intervals of remission, daily becoming of

longer duration; and it is specially gratifying when self-knowledge returns, interest in surroundings is displayed, and neatness of dress is studied—in fact when there is an indication of an appreciation of the amenities of existence, when the prayer of the Kilbarchan weaver is answered—in moderation.

And so we inevitably come back to the initial stage of this discussion, the importance of somatic conditions in relation to the mental states. Prognosis in insanity must proceed upon a wide and careful review of the whole circumstances affecting the individual, who is in a degenerative condition physically and therefore mentally. All that goes to make up that degenerative condition must be separately investigated and summed up. The elements of prognosis are analytical and synthetical, and it is determined by the nature of the degree of the involvement of the organism in the widest sense. If all the functions are involved, if the degenerative process is universal and intractable, the future of the individual is desperate indeed; if the defect is partial and amenable to treatment naturally the case is more hopeful as these limitations of involvement decrease. In that sense how hopeless is the case of pernicious anaemia in which the mental manifestations are the direct result of an impoverished brain. For a time it may be possible to draw upon the reserve of red blood corpuscles but the stock is not inexhaustible. It is in consonance with these observations that the toxic theory of insanity demands our most serious attention and excites our liveliest hopes. Prognosis can never be an affair of aphorisms; these *obiter dicta* require to be fitted into the general scheme of things; they are altogether too facile and too partial for our purposes.

Finally, on the general question of prognosis of insanity, we have been counselled to give a guarded opinion, because it is the unexpected that happens. An eminent physician once said that he was paid for an opinion, not for a prophecy. But an opinion is truncated and ineffective if it be only relative to the moment of delivery. The questions demanded of us are urgent and necessary: Is the family business to be wound up, are the pressing difficulties permanent or temporary, is the home life to be altered for a time or for ever, are careful plans for a career to be abandoned or postponed? I am impatient with a science that executes a strategic retreat before such a battery of questions. In the last resort, the kindly words of Horace recur to us:

"Tu ne quaesieris, scire nefas, quem mihi, quem tibi
Finem dederint, Lencore, nec Babylonis
Temptaris muros."

Yet it is a poor account of scientific medicine if it is to be recorded of us that our premonitions are of no more value than a Chaldean horoscope.

It is an excellent practice in which, throughout the years I have followed Sir James Crichton-Browne, to sum up the probabilities in the case-book on the reception of every patient. At least, it is a stimulating corrective for self-satisfied science; at best, an incentive to the careful study of every circumstance affecting each patient. For it is only by that study, indefatigable and personal, that advance is possible to us or to our profession. More steadfastly than ever our profession labours for the prevention of disease. That resolves in questions of eugenics, education in the widest sense, and a determined, informed study of all morbid phenomena.

THE MEDICAL TREATMENT OF CONGENITAL PYLORIC STENOSIS.¹

By G. A. SUTHERLAND, M.D. EDIN., F.R.C.P. LOND.,
PHYSICIAN TO THE NORTH-WEST LONDON HOSPITAL AND TO
PADDINGTON GREEN CHILDREN'S HOSPITAL.

THE symptoms and diagnosis of congenital pyloric stenosis are now well known and have been very fully described by Thomson, Cantley, Still, and others. The exact pathology of the affection is still unsettled and it may be that the results of treatment will throw fresh light on the subject. This paper deals only with the medical treatment by means of dieting and gastric lavage, a method of treatment to which Still has specially directed attention.² I propose to give brief notes of the last three cases which have come under my

¹ A paper read before the Clinical Society of London on March 8th, 1905.

² THE LANCET, March 11th, 1905, p. 632.

care and then to make some observations on the treatment generally.

CASE 1.—A male infant, six weeks old, a first child, was sent to me on May 22nd, 1906. The history was that the child had appeared to be healthy at birth but that vomiting occurred during the first week and had continued ever since. The vomiting was intermittent, sometimes only once a day, sometimes oftener, and usually occurred about 20 minutes after a feed. The vomited material was sometimes in large quantity and was violently pumped out. The child was losing weight steadily; the bowels were very constipated and acted only after the use of a glycerine suppository. The motions were small but healthy in appearance. The child was subject to flatulence, attacks of abdominal pain, and screaming attacks. He was always hungry and always ready for a feed. The diet had been the mother's milk and occasionally Allenburys food and peptonised milk had been tried and had been rejected. The breast milk when examined was found to be satisfactory, although the chief constituents were rather small in amount (proteids, 1.75 per cent.; fat, 2.4 per cent.; and sugar, 5.06 per cent.). The patient was a wasted, whining, unhappy looking infant weighing 7 pounds 6 ounces. On examination of the abdomen, after manipulation, the stomach was seen to be contracting strongly and peristaltic waves passed from the left to the right side of the abdomen. The pylorus was not felt. On the same night general convulsions supervened and lasted intermittently for 36 hours but passed off under the use of bromide and chloral rectal injections. The treatment ordered for the pyloric trouble was lavage once a day and a continuance of the breast feeding every two hours by day and every four hours at night, ten minutes at a time. On washing out the stomach a considerable amount of soft flocculent curd was removed, but this seemed to be of such a fine character that gastric digestion was evidently good. It was also considered that such a residue should pass easily through the pylorus unless abnormal spasm was present. The child remained under observation for three weeks during which the progress of the case was as follows. The lavage was carried out every day for the most part, sometimes every second day. The amount of residual food left in the stomach was found steadily to diminish. The vomiting became much less frequent and less violent, and towards the end of the time was trifling. The bowels came to act naturally without injections, and at times diarrhoea with green stools occurred. The employment of malt and oil, half a drachm thrice daily, seemed to produce gastro-intestinal disturbance. The child became much more comfortable and brighter with the cessation of the abdominal pain and vomiting. The weight at the end of three weeks was exactly the same as at the beginning. The infant then passed from my care and was treated on the same lines by a medical friend for a few weeks. Four and a half months later the following report was very kindly sent me by the practitioner under whose care the child had been placed. Steady improvement had taken place, interrupted only by a series of convulsions, which had been traced to the fact that the mother was menstruating at the time. The gain in weight was very slow but the infant now weighed ten pounds—i.e., almost three pounds heavier than when first seen. The weaning process was being carried out as the mother's milk was falling. The visible peristalsis of the stomach had passed off entirely two months previously.

CASE 2.—A male infant, three months old, was sent to me on Oct. 12th, 1906. He was healthy at birth, weighing 7½ pounds, and had been fed on cows' milk and water, which seemed to agree with him. At the age of five weeks vomiting had commenced and had persisted. It occurred once or more daily and was frequently very violent, the food being pumped out in large quantity. The bowels had been rather loose at first but later constipation had been marked, and for a month previous to my seeing the child the bowels had acted only after a glycerine suppository and the motions had been extremely small. The child slept badly, had frequent attacks of abdominal pain, and was always ravenously hungry. There had been a steady loss of weight going on for about two months. Many diets had been tried, including cows' milk and water, Mellin's food, peptonised milk, lacto, whey, and Allenburys food, but none of these had had more than a temporary effect on the vomiting. The child had been fed quite regularly every two and a half hours by day and somewhat less frequently by night. On examination the infant was found to be extremely emaciated and restless; he was whining, and he looked a picture of misery. His weight

was then 6 pounds 13 ounces. The temperature was normal. There was no sign of disease anywhere apart from the stomach. The abdomen was somewhat distended and gastric peristalsis was elicited by rubbing the abdominal wall. The contraction waves were very strong and passed right across from under the ribs on the left side to be lost on the right side of the abdomen. They were not apparently painful. The pylorus was not felt by me, but my friend Dr. Edmund Cautley, who kindly saw the case with me, was able to palpate it. As the infant was at the time on Allenburys food that diet was continued, and washing out of the stomach was performed daily. The vomiting rapidly diminished but complete digestion as ascertained by the results of washing out was not obtained until the feeding was employed every hour by day and every two hours by night. The bowels soon began to act naturally and a steadily increasing amount of faecal matter was present in the stools. The gain in weight was at first very slow and some weeks showed a loss of weight. The diet was varied with whey, peptonised milk, and cream, and a small quantity of malt extract, raw meat juice, and grape juice was given. The improvement was steady if slow and there was a definite change for the better in the infant's comfort and general appearance. The progress was interfered with at times by attacks of diarrhoea and later by an attack of influenza with bronchitis. The patient passed out of my care at the end of three months and was then a smiling active infant, keenly interested in all that went on, and weighed 9 pounds 6 ounces, a gain of two and a half pounds. The gastric lavage was still being carried out every second day as the influenza had left the infant very liable to gastric disturbance. Had it not been for this complication the washing out would probably not have been required so frequently.

CASE 3.—A male infant, three months old, was admitted to hospital on April 20th, 1906, suffering from marasmus. The child had been healthy at birth, but vomiting had come on a fortnight later and had continued. The diet had consisted entirely of the breast milk but wasting had been persistent. The bowels were constipated, acting only every second day, and there had never been diarrhoea. There was nothing of importance in the family history and the patient had presented no signs of constitutional disease. On admission the infant was found to be a typical example of "marasmus," very wasted, whining, always hungry, and sucking his fist. The rectal temperature night and morning was 98° F. The weight was six pounds. On physical examination the abdomen was found to be rather distended and tense and an inguinal hernia was present, but there were no signs of organic disease. A diet of equal parts of cows' milk, barley water, and lime water, half an ounce of each, was ordered, and the feeding to be every two hours by day (16 hours) and every four hours by night (eight hours). At the end of 24 hours the quantity at a feed was raised to three ounces. After three days half a drachm of cream was given thrice daily. Under this treatment the child seemed to improve, gained six ounces in weight in ten days, and seemed more comfortable. The amount of cream was then increased to half a drachm at each feed and this was quickly followed by vomiting. On returning to the former amount of cream the vomiting ceased. On May 9th it was noted that although the bowels only acted once a day and enemata were sometimes required, the motions were satisfactory. The infant, however, was losing weight, although without any obvious discomfort or vomiting. Three-ounce feeds of milk and lime water, equal parts, every two hours by day and every four hours by night, with half a drachm of cream and 15 drops of cod-liver oil thrice daily were ordered. Vomiting quickly followed and continued. On the 14th examination of the abdomen showed marked peristalsis of the stomach in waves passing from left to right and a diagnosis of congenital hypertrophy of the pylorus was made. Washing out the stomach daily was ordered. The food was now changed to peptonised milk and water and later cream, whey, plasmon, and plain milk-and-water were given at times. The amounts varied from three to four ounces at intervals of three or four hours. The washing out was continued daily and there soon came to be but a small residue present in the stomach two hours after a feed. When, however, it was reduced to every second day a considerable amount of food was found and the daily routine was resumed. The vomiting was entirely relieved and occurred very rarely and in a very mild form. At the end of three months' treatment the weight was 6 pounds 11 ounces, a gain of only 11 ounces. The peristalsis of the stomach after a

feed was as marked as ever. The temperature ranged between 96° and 97°. Treatment by opium had been given a full trial, up to seven minims of liquor opii sedativus daily, without the slightest effect. After consultation operative treatment was decided on. The operation of stretching the pylorus was performed by one of my colleagues on July 23th. A typical large, hard, contracted pylorus was found. The only point about the operation which calls for notice is that the peritoneum was ruptured at the duodenal end of the pylorus and was sutured. The infant suffered from a good deal of shock during the following few hours but improved after saline infusions. Rectal feeding was employed for 12 hours and then one drachm of whey in an ounce of hot water was given every three hours. The amount of whey was steadily increased. On August 1st it was noted that there had been no vomiting for three days; the child was taking food well and seemed comfortable. The addition of malt or cream induced vomiting and whey alone was given. On the 3rd the child did not take food so well and he died suddenly and unexpectedly on the same night. At the necropsy the abdominal conditions were found to be healthy, there was no peritonitis, and there was no apparent cause of death. This sudden and unexplained death in marasmic infants after a serious operation is, of course, of common occurrence. The question as to whether better methods of feeding and other food materials might not have led to a cure of the pyloric condition without operation must remain unsettled, but further experience has led me to believe that the treatment might have been improved upon.

Remarks on treatment.—I shall not refer to the surgical treatment of this affection, a subject which was very thoroughly considered at the Toronto meeting of the British Medical Association.² My hope and belief are that as our knowledge and experience of the medical treatment advance there will be fewer and fewer cases in which surgical intervention is called for.

1. *The objects aimed at.*—The aim of the medical treatment is to remove any source of irritation in the stomach which may maintain pyloric spasm and to keep the stomach free from any irritating food material, digested or undigested, which may excite pyloric spasm. Within recent years many cases of this affection have been seen in the post-mortem room, and as we looked at the hard hypertrophied tissue and the complete stenosis it was a common remark that only operative treatment could have relieved the condition. It must be remembered, however, that the pylorus has two functions, contraction and relaxation, and the fact that the muscular tissues generally are hypertrophied is no reason for assuming that only the power of contraction is retained. I believe that both these functions are present at birth and that there is in addition a congenital hyperplasia of the muscular tissues of the pylorus, as Cautley has so strongly insisted on. For a varying length of time, days or weeks in different cases, all goes well and the pylorus acts normally. But a time comes, even in the most carefully fed cases, when some irritating (undigested) food lies in the stomach and the pylorus contracts strongly and remains closed. Vomiting follows. The repetition of such a condition gradually induces a more or less continuous spasm of the pylorus, or at least a spasmodic contraction which seriously interferes with the normal emptying of the stomach. It may be that in some cases, as in those recorded by Willoughby Gardner, and Still, it is possible solely by careful dieting and the use of a food leaving little residue in the stomach to check this over-action of the circular fibres of the pylorus. Such cases are probably rare but they support the view that there is no inherent vice in the pylorus. They are rare because a diagnosis could seldom be made at a stage when such treatment would usually be effective. By the time a diagnosis can be made with certainty the spasm of the pylorus is established and as the result hypertrophy and dilatation of the stomach have followed. We have then to deal with a fastidious, irritable, dog-in-the-manger pylorus, which must be humoured and soothed and deferred to in every way. It is not to be supposed that even in marked cases the pylorus never relaxes. At operations it has frequently been found that the hypertrophied pylorus can and does relax and will often admit the little finger without difficulty. In many cases the presence of faecal matter in the stools and the absence of vomiting for a week or more show that food is passing through the pylorus. The gravity of the affection lies in the fact that it does not do so

in sufficient quantity for the nutrition of the infant. These would appear to be the grounds on which medical treatment may be expected to do good and, expressed in other words, the aim of the treatment is to restore the function of relaxation of the pylorus which has been in abeyance owing to the more powerful action of the constrictor muscular fibres.

2. *The food and feeding.*—Although the stomach is much dilated and is capable of holding a large amount of food, small feeds are called for in order to secure complete digestion. Two or three ounces will be found sufficient at a meal and in bad cases one-ounce feeds are advisable. In order to supply a sufficient amount of nourishment the number of meals must be increased. An infant, aged one month, should be fed every two hours day and night and in bad cases, when only small quantities are allowed at a time, every hour by day. This may have to be carried on for some months unaltered but if the progress of the case allows of it one will naturally try to increase the amount at a meal and feed less often as time goes on. If the infant will sleep for longer intervals at night he should be allowed to do so but hunger will usually awake him with great regularity. Small quantities, from one drachm to four drachms, of plain water or dill water or cinnamon water may be given between the feeding times if the child is thirsty or wakeful. The difficulty in the complete digestion of the food in the stomach lies in the proteins and the fats, more especially the latter. Over and over again I have found the addition of cream or cod-liver oil bring on gastric irritation and vomiting.

If good breast milk is available it is the best food. A chemical analysis of the milk should be made and one would prefer to have rather a low amount of all the chief solids. The fat should not be more than 3 per cent. The quantity given at a time must be regulated by the duration of the feed, five or ten minutes as the case may be. Unfortunately, in many of these cases one finds that suckling has been stopped in the belief that the milk was disagreeing with the child and one of the most useful adjuncts in the treatment is lost.

If artificial feeding is employed, cows' milk as usually modified does not act well owing to the heavy curds which remain in the stomach. The foods which have proved most successful in my experience are peptonised cows' milk (without added cream), whey, and Allenburys food (No. 1). This last I take as a type of foods which are not in themselves suitable for healthy children, but which are capable of very complete digestion in the stomach. In addition, malt extract, raw meat juice, and grape juice have been given daily in small quantities. No doubt other foods may be found equally efficacious and the question of the suitability of the food is to be decided by the state of the stomach contents after washing out.

3. *Gastric lavage.*—The stomach should be washed out once a day for a prolonged period, and in bad cases this proceeding may be required twice daily for a time. It is quite a simple process in young infants, and if properly carried out leads to no discomfort or disturbance. It should be done when under normal conditions the stomach is empty—i.e., two, or two and a half hours after a meal, as the case may be. The value of the information gained from the nature of the stomach contents cannot be over-estimated. The wash-out should show a small amount of soft flocculent matter, which tends to get less in successful cases as time goes on. If, on the other hand, a large amount of matter is washed out, or undigested curds, it is clear that the food is not properly digested and will maintain the pyloric spasm. Dr. Cautley has pointed out that in many cases the mere washing out of the stomach systematically will check the vomiting and that this may prove misleading. This is perfectly true, and therefore one must examine carefully the nature of the stomach contents in order to see whether the residue would be likely to pass the pylorus. If this residue is of the soft flocculent nature described above one may reasonably expect that it can, and will, prove non-irritating, and will eventually pass naturally through the pylorus. Other indications of improvement must also be looked for and will be referred to later. For the observation of these points and for the lavage to be of any real value it is of the first importance that the physician should carry out the proceeding himself and not entrust it to any nurse however skilled and experienced she may be. Gastric lavage is not only beneficial to the infant but is also the means of showing the physician how to regulate successfully the food and feeding.

4. *Signs of progress.*—1. The vomiting ceases. This usually follows quickly after lavage and suitable feeding have been carried out. 2. The bowels act naturally. This is a very important sign of progress, for it is in such marked contrast to what occurs in untreated cases. In the latter constipation is the rule, artificial aids per rectum being very often required, and the motions contain little faecal matter. After the medical treatment has been begun the bowels act two or three times a day without artificial stimulation and the motions are larger and consist of faecal matter. 3. The stomach peristalsis becomes less marked, less strong, and gradually passes off. The complete disappearance of peristalsis may take some weeks or months, but the lessening is usually seen early in successful cases. 4. The discomfort, pain, apathy, and constant whining of the infant are removed and are replaced by a placid and comfortable state, in which even smiling is gradually evolved. 5. The nutrition of the infant is improved. This is manifested in a healthier colour, in increased activity of the limbs, and in a slow gain in weight. It is very important to remember that these infants cannot be fattened rapidly, that any attempt to secure this will probably end in disaster, and that the less weighing there is the better, especially if there are anxious relatives about. The most suitable foods are not fattening ones, and any excess of food is apt to produce disturbance either in the stomach or the bowel. On the other hand, the vital powers of the infant can be very much improved, and the disordered functions restored to healthy action, by a simple diet, and the fattening materials can be reserved to a later period. Progress in the infant is usually marked by a slow increase in weight, somewhat fluctuating at first, but tending to become steady as time goes on.

5. *Complications.*—A common complication in the course of treatment is diarrhoea. The bowel in such cases has been out of use for some time and is consequently unprepared for the food material which now passes through the pylorus. Hence probably arises an irritative form of diarrhoea. The best treatment is to reduce the amount of food given by one half and to keep it so until the diarrhoea has ceased. At the same time half a grain of grey powder may be given twice or thrice daily. When the diarrhoea ceases the amount of food can be again gradually increased. Such diarrhoea is always serious and may prove fatal. When vomiting occurs no food should be given for two hours in order to rest the stomach. Sips of hot water may be given if the child is thirsty. Intestinal flatulence is to be treated, like diarrhoea, by a temporary reduction in the amount of food.

6. *Medicinal treatment.*—The use of anti-spasmodic drugs such as opium and the bromides has not proved of the slightest value in my experience. Of course, infinitesimal doses of opium cannot be expected to do any good, but I have pushed the drug to its full physiological effects without any benefit whatever. Nor does it appear likely that the drug would have any special action on the circular fibres of the pylorus and fail to affect the longitudinal fibres to an equal extent. In cases of marasmic infants suffering from this affection, with all the tissues dried up, the use of saline injections both subcutaneously and per rectum has seemed beneficial. From four to ten ounces of normal saline solution can be given daily and will act as a restorative until the improvement of the pyloric function allows of the entrance of a sufficient amount of fluid into the system by the natural route. In cases in which the infant is much reduced or has a subnormal temperature brandy, up to half a drachm daily, will be found of service as a general tonic. The administration of cod-liver oil by intunction, if it be of any value, would appear to be specially suited to the conditions present in this affection. I have only employed it once and in that case a skin eruption quickly followed and led to its discontinuance.

Whimpoles street, W.

PASSMORE EDWARDS COTTAGE HOSPITAL, LISKEARD.—The annual meeting of the subscribers to this hospital was held on Feb. 26th. The medical report stated that 78 in-patients and 30 out-patients had been treated during 1906, being the highest number on record. The financial statement showed a small favourable balance. The committee decided to elect all the members of the medical profession in the town as honorary members of the staff, with Dr. R. H. Lucy as honorary consulting surgeon, Mr. J. R. Rolston as honorary ophthalmic surgeon, and Mr. W. H. Lyne as honorary dental surgeon.

ON TERTIARY SYPHILITIC FEVER AND THE VISCERAL AND OTHER CHANGES CONNECTED WITH IT.

BY F. PARKES WEBER, M.D. CANTAB., F.R.C.P. LOND.,
PHYSICIAN TO THE GERMAN HOSPITAL, LONDON, AND THE MOUNT
VERNON HOSPITAL, HAMPSHIRE.

A GOOD deal has been written on the subject of fever, especially protracted fever, in tertiary syphilis,¹ but my attention was first directed to the subject by Mr. Campbell Williams and by the patient himself whose case Mr. Williams described at the Clinical Society in 1900 as "A Case of Late Syphilitic Pyrexia (Intermittent Essential Fever of Syphilis)."

The first patient, a married woman, aged 36 years, was under my care at the German Hospital from May 1st to June 17th, 1906, and again from August 27th to Sept. 10th, 1906. She had previously been under my care at the Mount Vernon Hospital. The patient's husband, a fairly healthy-looking man, admitted that in 1893 he had a sore on his penis. He was only three or four weeks under treatment for it and as far as he knows there were no secondary symptoms. (The husband's history was not, however, obtained till the clinical evidence of syphilis in the patient's case was conclusive.) The patient had had no children since 1893, but of the two children born previously one was living and healthy and the other died in infancy. She had had no miscarriages. She had certainly been accustomed to indulge somewhat freely in whisky. Up to 1900 she enjoyed fair health but about that time a good deal of the hair of her head came out and she began to suffer from depression, languor, occasional vomiting, and occasional night-sweats. About 1902 she had "rheumatism," principally in her knees. In December, 1904, she first brought up blood and became subject to nausea, vomiting, and inability to take food. In 1905 she occasionally brought up blood (hæmatemesis or hæmoptysis); usually she first coughed and then vomited, the vomiting being followed by bringing up the blood. There was no history of jaundice. From childhood she had often had sore throats. She dated her present deafness from 1905. In August, 1905, sores formed about her left ear which were preceded by lumps. From Dec. 1st, 1905, to March 7th, 1906, she was in the Mount Vernon Hospital. On admission she was found to have considerable enlargement of the liver and spleen, pains in the lower extremities, and an irregular type of fever, occasionally over 102° F. On two occasions (Dec. 4th and Jan. 8th) she was said to have had coloured expectoration, but no definite signs of any disease in the thoracic organs could be discovered except some dullness at the base of the right lung corresponding to the enlargement of the liver. On one occasion I noted that the liver and spleen were hard, had a

B. Fletcher, Syphilitic Fever with a Report of Three Cases, New York Medical Journal, June 22nd, 1901, p. 1065; F. Klemperer, Ueber Pleber bei Syphilis der Leber, Zeitschrift für Klinische Medizin, Berlin, 1904, vol. iv., p. 178; A. Birt, The Fever of Late (Visceral) Syphilis, Montreal Medical Journal, October, 1905, vol. xxxiv., p. 748; L. D'Amato, Sulla Febbre Sifilitica Terziaria, La Riforma Medica, Naples, March 10th, 1906, No. 10, p. 253. Both Birt and D'Amato refer to many papers on the subject. F. Klemperer also alludes to observations by G. Klemperer, O. A. Ewald, and others. J. S. Bristowe (Clinical Society's Transactions, London, 1886, vol. xix., p. 249) and T. D. Savill (Clinical Journal, London, Dec. 1st, 1897, p. 57) have both drawn attention to the occurrence of chronic hectic fever connected with gummatous disease in congenital syphilis. One of the earliest authors to draw attention to the possible occurrence of a hectic type of fever in tertiary as well as in early syphilis was C. Bäumler, who whilst still in London wrote a paper, Ueber das Verhalten der Körperwärme als Hilfsmittel zur Diagnose einiger Formen Syphilitischer Erkrankung, Deutsches Archiv für Klinische Medizin, Leipzig, 1872, vol. ix., pp. 397-432. Fever up to about 102° F. is mentioned in 1872 vol. ix., pp. 397-432. Fever up to about 102° F. is mentioned in H. Weber's account (Transactions of the Pathological Society of London, 1896, vol. xlv., p. 152) of a case of very extensive tertiary syphilis, little disease in the liver, lungs, bronchial glands, dura mater, cranium, and sternum. J. E. Gunz, a pupil of Wunderlich, was the first to make accurate thermometric observations on the fever of the early stages of syphilis, the occurrence of which was already known to John Hunter.

² Transactions of the Clinical Soc.

fairly even surface, and were not painful or tender. They gave me the impression of being more or less adherent to the abdominal wall and I had little doubt of the existence of perihepatitic adhesion. On Jan. 9th, 1906, treatment by mercurial inunction and the internal use of potassium iodide was commenced, with the result that on the 12th she had no fever and the fever remained absent from that date till the treatment was discontinued on the 29th. On Feb. 3rd the fever recommenced and antisyphilitic treatment was not then regularly carried out as the patient appeared to be suffering from follicular tonsillitis with glandular enlargement on the left side of the neck. The fever, however, which was of a hectic type, persisted, and early in March typical gummatous disease with perforation of the soft palate having developed renewed antisyphilitic treatment was started on March 4th. On March 6th she remained free from fever but unfortunately left the hospital on the following day.

On May 1st, 1906, the patient, looking very cachectic, was admitted under my care at the German Hospital and treatment by intramuscular injections of salicylate of mercury, together with the internal use of potassium iodide and Zittmann's weak decoction, was at once commenced. On May 1st and 2nd the evening temperature reached 100° and 102° F. respectively, but after that there was no more fever till she left the hospital on June 17th. She quite lost the cachectic appearance and gained considerably in weight. The ulcerated perforation of the soft palate soon began to have healthy edges and had certainly contracted by the time she left the hospital, but the liver still remained enlarged, the edge being felt three fingers' breadth below the costal margin in the right nippleline.

On August 27th she was readmitted to the German Hospital under my care suffering from tertiary syphilitic peritonitis over both tibiae and about the left elbow-joint, &c. Ophthalmoscopic examination showed a few foci of chorioretinitis in both eyes (Dr. C. Markus). The evening temperature was 102°. Potassium iodide and Zittmann's decoction were given and on August 28th (the day after admission) treatment by intramuscular injections of salicylate of mercury was again adopted. Rapid improvement in the periosteal affection followed the commencement of the treatment and there was practically no fever from August 30th till the patient left the hospital on Sept. 10th. Perchloride of iron was likewise administered. I saw her again on Jan. 27th, 1907, when she told me that on Jan. 20th at about 3 p.m. she had vomited about one and a half pints of dark blood. In spite of this attack of hæmatemesis she looked fairly well, and she had apparently enjoyed fair health since she left the hospital.

This case on four different occasions illustrates remarkably rapid disappearance of the fever on the commencement (within two days or so) of antisyphilitic treatment. The fever in February, 1906, was of a hectic type and one can easily understand that tertiary syphilitic pyrexia may be mistaken for septic fever, or may be supposed to be due to pulmonary tuberculosis, especially when, as in the present case, a history of blood-spitting and night-sweats can be obtained. Chronic hectic fever accompanied by occasional night-sweats and blood-spitting has sometimes doubtless led to a suspicion of pulmonary tuberculosis, even in the absence of any physical signs pointing to local disease in the lungs. Moreover, slight differences in resonance between the two sides, such as are often found on examining the chests of quite healthy individuals, have probably sometimes been interpreted as confirming a suspicion of consumption. It is easy to find (or to imagine) slight physical signs to support a diagnosis of lung disease suggested by hectic fever, emaciation, progressive weakness, &c.

E. G. Janeway² wrote in 1898 a well-known paper on the Danger of Error in Diagnosis between Chronic Syphilitic Fever and Tuberculosis. O. Gerhardt³ alluded to three cases of hepatic syphilis in which the presence of hectic fever led to a diagnosis of pulmonary tuberculosis. The three patients were sent to sanatoriums for consumption, but were afterwards cured by antisyphilitic (mercurial) treatment. A. Birt⁴ says that the fever of late syphilis may be occasionally associated with chills, night-sweats, and emaciation, so as to simulate tuberculosis, sepsis, or malaria, but especially tuberculosis. In his case it was only when a tender node on one rib was detected that the patient admitted having contracted syphilis 11 years previously. In regard to the employment of the tuberculin test Birt

concludes that it is of little value for distinguishing the syphilitic from the tuberculous cases and may be faulty. Indeed, the repeated sharp rises of temperature and occasional rigors in many cases of syphilitic fever make tuberculin altogether unreliable for diagnostic purposes and, as a matter of fact, owing to the presence of fever, its employment is, in my own opinion, absolutely contra-indicated.

F. Klemperer⁵ mentions having seen a young man with a remittent type of fever who had been treated by tuberculin, &c., for pulmonary tuberculosis seven years after primary syphilis, and in whom mercurial treatment removed the fever. He likewise quotes Veress⁶ as describing the case of a woman with pulmonary syphilis and recurrent ague-like attacks of shivering and fever. She was first supposed to have malaria and then pulmonary tuberculosis, but the appearance of a gumma on the leg led to the recognition of the syphilitic origin of her illness and to its speedy cure by antisyphilitic treatment.⁷ Fever is, however, no more a necessary accompaniment of pulmonary syphilis than it is of hepatic syphilis.

Sidney Phillips⁸ in 1889 pointed out that syphilitic fever might easily be mistaken for malaria. His case had definite ague-like chills and resembled tertian fever. There were, apart from what seemed to be erythema nodosum, no definite local lesions, but the symptoms yielded promptly to antisyphilitic treatment. One of Fletcher's three cases⁹ of syphilitic fever was characterised by intermittent chills with fever and was treated first as a case of malaria, but afterwards yielded readily to antisyphilitic treatment. Veress¹¹ quotes a case of Eckert, of Tientsin, in which tertiary syphilitic fever was accompanied by shivering attacks and enlargement of the spleen so as to simulate a form of malaria. Confusion with malaria is, of course, most likely to occur in malarious countries and when the spleen is enlarged and when there are definite attacks of shivering.

Needless to say, typhoid fever, malignant endocarditis, and febrile cholelithiasis may all be thought of in cases of tertiary syphilitic fever. One of the cases recorded by Fletcher¹² was for weeks suspected of being a case of typhoid fever and was treated as such, but the correct diagnosis was established by the discovery of periosteal thickening over the clavicles and by the cessation of the fever after the beginning of treatment with potassium iodide. The presence of "tertiary syphilitic diarrhoea"¹³ in such cases would still further increase the clinical resemblance to typhoid fever. Definite clinical signs of valvular disease may, as is well known, be absent for a long time in cases of malignant endocarditis, and syphilitic fever of intermittent or remittent type might be mistaken for early malignant endocarditis before the development of a definite murmur; such a mistake would be more likely to occur if there happened to be an old valvular lesion present, of rheumatic origin or from any other cause, or if a so-called "anæmic" or other murmur not due to organic valvular disease were to be heard.¹⁴

The occurrence in tertiary syphilis of enlargement of the liver, with local tenderness due to perihepatitis, and accompanied by pyrexia, shivering attacks, and a certain degree of jaundice, might make one think of cholelithiasis and its complications. In one of G. Klemperer's¹⁵ cases of tertiary syphilitic fever accompanied by enlargement and tenderness of the liver with some jaundice an operation to search for a hepatic abscess was to have been undertaken, but antisyphilitic (mercurial) treatment was tried and led to rapid and complete cure. J. S. Bristowe,¹⁶ in the case of a boy, aged 15 years, with hectic fever and hepatic enlargement, twice explored the liver with trocar and cannula (hoping to find an abscess) before evidence of congenital syphilis was obtained; antisyphilitic treatment led within four days to the cessation of the fever, which had lasted

two months and had been accompanied by occasional rigors and night-sweats.

In my patient the enlargement of the liver and binding down (perihepatitis) of the organ were doubtless partly the result of local tertiary syphilitic processes, though alcohol may likewise have had a share in the causation. It is noteworthy in what a large proportion of cases of tertiary syphilitic fever there have been signs of liver disease. In each of L. D'Amato's¹⁷ three cases of fever (eight to 16 years after the primary infection) there was evidence of hepatic complication; in his first case there was perihepatitis, in the second there was probably a gummatous change, and in the third there was jaundice. A. Birt¹⁸ thinks that it is chiefly in cases in which the syphilitic process affects the liver that late syphilitic fever occurs. F. Klemperer¹⁹ describes two cases of chronic fever of an intermittent type accompanied by shivering attacks in which no organic changes could be detected, except in the liver (enlargement, tenderness, and slight jaundice). The diagnosis seemed to lie between obscure suppuration (septic fever), tuberculosis, and malaria, until the possibility of a syphilitic origin was thought of; antisyphilitic treatment led to a rapid cure in both cases. He points out that the intermittent type of fever with enlargement of the liver and occasional shivering attacks was likewise present in cases described earlier by G. Klemperer,²⁰ O. A. Ewald,²¹ and others. C. Gerhardt, who was well acquainted with febrile cases of syphilis of the liver, writing in a paper on the subject in 1900,²² said that though most patients with hepatic syphilis were free from fever, in some cases the hepatic affection was accompanied by fever which simulated other diseases, though the satisfactory results of antisyphilitic treatment proved it to be due to the syphilis. Even the recent hæmatemesis in my case may possibly be due, not to ordinary gastric ulcer or hepatic cirrhosis (dilated veins in the stomach or œsophagus), but to syphilitic disease of the stomach. A. Casaris-Demel²³ has narrated the case of a man who died suddenly from intra-peritoneal hæmorrhage which the necropsy showed to proceed from a perforating syphilitic ulcer of the stomach. Though it must be acknowledged that undoubted syphilitic gummatous disease of the stomach and intestines is rare a good many cases have been verified by post-mortem examination or by the results of treatment.²⁴

In tertiary syphilitic "dyspepsia" and tertiary syphilitic diarrhoea the result of antisyphilitic treatment may be very striking. In the out-patient department of the Mount Vernon Hospital I saw on Jan. 18th, 1902, an extremely cachectic-looking young woman, aged 26 years, with gastrointestinal symptoms. Some time before coming to the hospital she commenced to suffer from anorexia and vomiting after meals and she had lost flesh and strength. She had had diarrhoea for about a month and on drinking a little milk she would vomit or have a diarrhoeal motion. I gave bismuth at first without any great benefit, but on Feb. 1st the presence of periosteal nodes on the tibia, which were tender to the touch, made it clear that she was

suffering from active tertiary syphilis; moreover, the was a history of previous pains in the head, back of the neck and extremities worse during the night. 30 grains potassium iodide and some quinine were given three times daily. A good effect was felt in regard to pains after about three doses, and she rapidly recovered her appetite and cheerfulness; she could sleep well and walk well, and began to look in blooming health. Unfortunately in this case, the woman was an out-patient, there is no record of the temperature.

A man, aged 37 years, a German sailor, was admitted under my care at the German Hospital on Jan. 17th, 1900. He was cachectic-looking and suffered from fever, chronic swelling and stiffness of the right elbow-joint, and tenderness on various bones. The history was that as a soldier in 1890 he contracted a hard chancre on the penis, for which he seems to have been treated with mercury. He does not recollect the appearance of any secondary eruption. In 1891 he was under my care at the German Hospital with fever and a polyarticular joint affection which I then regarded as acute rheumatism. The patient had, however, likewise inflammation of the left epididymis and testicle; on one occasion I noted some tenderness at the junction of the sixth left costal cartilage with the sternum, and there was a tender swelling between the tibia and fibula of the right leg. I thought also of the possibility of there being a syphilitic element in the case, although apparently at that time I was not aware of the patient having had a chancre. It may be specially noted that the treatment included the use of iodide of potassium besides sodium salicylate and quinine. About two and a half years (1904) ago he suffered from ulceration of the palate (which led to perforation), and also from headache and fever, for which he was treated with benefit by potassium iodide in a hospital at Rotterdam. A little while afterwards the present affection of the right elbow-joint commenced with pain and swelling. About one year ago he had an abscess to the outer side of the right eye, which left a depressed scar. On admission to the German Hospital in January, 1907, the patient presented undoubted evidence of recent and past tertiary syphilitic trouble. There were an old perforation of the hard palate, old soarring of the soft palate, and the depressed cicatrix (already mentioned) close to the right eye. The original cause of the chronic swelling, stiffness, and tenderness of the right elbow-joint would not by itself, have been obvious, but there were tender swellings on the eighth right rib, on the right clavicle, and on the manubrium sterni, all of which suggested active tertiary syphilis; moreover, the patient said that on several previous occasions he had suffered from swellings on the ribs which disappeared again. A chain of enlarged lymph glands from the right elbow upwards along the brachial artery could be felt and did not seem to be tender. There was no evidence of disease in the thoracic and abdominal viscera, excepting slight impairment of resonance over the upper right part of the thorax (this was possibly, however, connected with the disease of the right clavicle) and slight enlargement and tenderness of the liver. The urine was free from albumin and sugar. Examination of the blood (not till Jan. 29th) gave: hæmoglobin (by Haldane's method), 58 per cent. of the normal; red cells, 3,575,000 per cubic millimetre; white cells, 6440. There were no retinal or choroidal changes. The patient was treated by mercurial inunction (five grammes of the mercurial ointment of the German Pharmacopœia daily) and was given an iron medicine internally. Some of the tenderness, at least that of the rib, sternum, and liver, disappeared, but the swelling of the right elbow and the tenderness of the right clavicle persisted. The anaemia diminished, so that on Feb. 10th the red cells numbered 4,200,000 per cubic millimetre, white cells 10,250, and hæmoglobin (by Haldane's method) about 73 per cent. of the normal. The temperature, which had been 100°-101° F. on the first three evenings, remained after that mostly below 100°, but the fever did not quite disappear. The mercurial inunction was discontinued on Feb. 11th and from the 21st the evening temperature was never below 100° until 15 grains of potassium iodide were given three times daily. The iodide was prescribed on the 26th; on the evenings of the two following days the temperature was 101°, but on the next three evenings it was only 99°-4°, 98°-2°, and 97°-8° respectively. From March 1st small doses of arsenic and iodide of iron were given as well as the iodide of potassium. It is not surprising that the fever was somewhat resistant to the inunction in this case, since Roentgen photographs

(March, 1907) of the right elbow and of part of the chest point to there being extensive gummatous disease of the right clavicle and lower end of the right humerus.²¹

Gummatous disease of periosteum and bone is certainly at times associated with fever. T. D. Savill²² has recorded a fatal case of congenital syphilis in a boy, aged 16 years, with extreme cachexia simulating pernicious anaemia, the necropsy showing gummatous masses over the frontal portions of the brain and gummatous disease of the petrous bone, ribs, and clavicle. In Savill's case the pyrexia was of an intermittent type, rising to 100°-102° in the evenings. Although my cases showed obvious changes in the abdominal viscera or bones, there may doubtless be cases of long-continued, apparently "idiopathic," pyrexia, in which on examination no signs of organic disease can be found to account for the fever, but which may really be connected with tertiary syphilitic changes in the viscera in situations where such changes would escape detection by the ordinary methods of physical examination. In January, 1906, I saw a man, 45 years of age, who had suffered from primary and secondary syphilis in 1889. He had been treated at Aix-la-Chapelle in 1893 and about 1902. He had suffered from evening fever (100°-101°) for about five months from July, 1905, but this fever had just disappeared on his voyage home from India. He complained of a little discomfort in the hepatic region, but I could find no physical signs of any disease, except slight wheezing over the lungs, and there was a history of asthmatic symptoms. I regarded the chronic pyrexia as being very likely connected with his syphilis and the medical man at Aix-la-Chapelle, to whom at my advice he went for another course of antisyphilitic treatment, thought that it was connected with perihepatitis. It is very probable that in some cases of tertiary syphilitic fever the fever may cease without antisyphilitic treatment, just as gummatous disease may in some cases heal up without any specific measures being adopted. L. D'Amato²³ writes amongst his conclusions that syphilitic fever may cease spontaneously without specific treatment, but then, just like the other syphilitic manifestations, it is more likely to recur. I have lately been looking over some notes of a case of a long-lasting pyrexia of unknown origin in which recovery ultimately took place but in which I regret that antisyphilitic methods were not given a fair trial. The patient, a man then aged 54 years, was admitted under my care on Nov. 15th, 1898, with a history of four weeks' illness and the fever, which was of intermittent or remittent type and associated with rigors, lasted till Dec. 21st. Malarial parasites were not found in the blood and he did not react to quinine and no satisfactory explanation of the fever was forthcoming. He had some oedema of the lower extremities, crepitations at the bases of the lungs, temporary slight enlargement of the liver, and superficial glossitis; there was a history of a chancre ten years previously. This man was again temporarily under treatment in March and April, 1899. He then had slight jaundice, with crepitations at the base of both lungs and decided dulness at the base of the right lung. But on that occasion there was scarcely any fever (the temperature never reached 100° except on the first evening) and the jaundice and the pulmonary signs readily cleared up. At present (1907) I hear that he is in fairly good health.

Harley-street, W.

A RADIOGRAPHIC SURVEY OF 170 CASES CLINICALLY DIAGNOSED AS "COLLES'S FRACTURE."

BY REGINALD MORTON, M.D., O.M. TRIN. TOR.,
F.R.C.S. EDIN.,
MEDICAL OFFICER IN CHARGE OF THE ELECTRICAL DEPARTMENT,
LONDON HOSPITAL.

STATISTICS regarding any disease or injury are always of interest and value to medical men, especially when the figures are based on the careful observation of a relatively large number of cases; and among fractures probably no single one possesses such a widespread interest among the profession as that of the lower end of the radius close to its articulation with the carpus, which is generally known, after

the surgeon who first described it, as "Colles's fracture." Until the advent of the x rays it will be remembered that many points regarding it were the subjects of considerable controversy, such as the distance of the line of fracture from the carpal border or the character of the displacement. Before 1895 we were never taught that damage to the styloid process of the ulna was a common accompaniment of this injury; in the several books published in the pre-Roentgen ray days which I have consulted it is not even mentioned. This is not surprising when we consider the necessary imperfections of clinical examination and also the fact that the opportunity for making a dissection seldom arose. Roentgen's discovery has changed all this, and thanks to the work of Lynn Thomas and others new and valuable evidence has been forthcoming.

Considering the large amount of material available at the hospital with which I have the honour to be connected, it seemed advisable to make an attempt to obtain some more or less reliable data, and accordingly instructions were given to the receiving room officers to send all cases diagnosed as Colles's fracture to be radiographed—preferably before being put up. This was carried out as systematically as possible for about 12 months, and it was in only a comparatively few cases—those arriving between Saturday evening and Monday morning, when the radiographic department was closed—that the radiograph was taken while the dressing was in place. Owing to the large amount of practice obtained by the receiving room officers before and during their term of office, their skill in diagnosis may be taken as at least equal to that of the profession generally, and it may also be taken that in every case the history, signs, and symptoms, so far as could be elicited, pointed to the presence of this form of fracture. The radiographic procedure presented no special features. By screening one-half of the plate with a piece of sheet lead it was easy to get an anterior and an ulnar view side by side on a 8½ by 6½ inches plate. Considerations of economy in both time and plates prevented other views being taken, and for the reason that in an ulnar view it is difficult, and in many cases impossible, to get a side view of the line of fracture of the radius the amount of accurate information available from the present series is not complete. A side view of the wrist with the radius next the plate, under ordinary arrangement of apparatus, involves a more or less constrained position to a person suffering from this fracture, and it is thus very difficult to avoid some movement during the period of exposure. To overcome this difficulty I have devised a support for the wrist, plate, and tube with which it is not necessary to move the forearm while the two exposures are being made. For the radial side view the plate is placed vertically and the tube is lowered to the same level as the wrist which lies comfortably upon its support.

The preparation of a second series of cases in this way is now in progress, the results of which I propose to publish as soon as complete, and it is hoped that 200 cases may be collected within a reasonable time.

In making up Table I. it should be mentioned that a

TABLE I.

PART I.

Total number of cases examined, 170.

The radius only fractured	155 cases.
The ulna only fractured	2 "
Both bones fractured	7 "
Fracture of the trapezium	1 case.
No fracture detected	5 cases.
Dislocation of the wrist-joint complicating fracture	3 "
Fracture of the styloid process of the radius	20 "
Fracture communicating with the wrist-joint	25 "
Fracture of the styloid process of the ulna	18 "
Separation of one or both epiphyses	11 "

PART 2.

The line of fracture of the radius—	
Transverse	120 cases.
Oblique	13 "
Irregular	4 "
Obliquely transverse	3 "
Transverse, but line irregular	22 "
The average distance of the line of fracture from the carpal border—	
1 inch	2 cases.
2 "	16 "
3 "	31 "
4 "	62 "
5 "	17 "
2 inch	11 cases.
1 "	2 "
1½ inches	1 case.
1½ "	1 "

²¹ The red corpuscles have now (March 12th) increased to 5,000,000 in the cubic millimetre and the patient has quite lost his former appearance of cachexia. There has been no fever since March 1st.

²² Loc. cit.

from the lymphatics of the legs escaped into the bladder. There was no inflammation in the urinary tract and the kidneys were normal. Purulent pericarditis, hypostatic pneumonia, and acute bronchitis were present. This was the fourth published case of a necropsy on a patient with non-tropical chyluria. There were strong reasons for believing that all cases of chyluria, whether due to filaria or not, were caused by the same anatomical abnormality—viz., obstruction to the thoracic duct or large abdominal lymphatics, with consequent dilatation of abdominal and pelvic lymphatics and rupture of a dilated lymphatic into the urinary tract. The obstruction in filarial chyluria appeared to be due to a fibrous stenosis of the thoracic duct, secondary to inflammation brought about by the presence of filaria at some earlier period. The parasites themselves had never been found blocking the thoracic duct. As the obstruction, when once produced, would be permanent it would remain after the filaria had all died out. Hence cases, such as the present one, in which the patient had been abroad 20 years before the onset of the chyluria, might quite well have been due to an old infection with filaria which had completely died out, leaving the obstruction in the thoracic duct. Presumably the rupture of a dilated lymphatic into the bladder occurred only in March, 1906. In non-filarial cases the obstruction was probably due to some other parasite, or more frequently to caseous glands or other tumour pressing on the duct from without. Hence the distinction between tropical and non-tropical chyluria was artificial and not warranted by the pathogenesis of the two conditions.

Mr. T. M. HAMELL said that he had made observations on a subject in which chyle came from a chylous fistula. The rate of appearance of fat in the chyle was dependent on the condition of the fat and whether it had a high or low melting point. The fats with a low melting point appeared more rapidly than those with a high melting point. He had never been able to detect dextrose in the chyle. He asked whether by any operation it was possible to connect the part of the thoracic duct below the lesion with that above it.

Dr. HERTZ, in reply, said that he had made no experiments with regard to the rapidity of absorption of the fats with the high or low melting points, but for the ordinary fats of food it took only half an hour before they began to appear in the urine. Exercise increased the lymph flow and the rapidity with which the fat appeared in the urine.

CLINICAL SOCIETY OF LONDON.

The Medical and Surgical Treatment of Congenital Pyloric Stenosis.

A MEETING of this society was held on March 8th, Mr. H. H. CRUTTON, the President, being in the chair.

Dr. G. A. SUTHERLAND read a paper on the Medical Treatment of Congenital Pyloric Stenosis, which will be found at p. 725 in the present issue of THE LANCET.

Dr. A. F. VOELCKER read short abstracts of seven cases of Hypertrophic Pyloric Stenosis in infants who had been under his care at the Hospital for Sick Children, Great Ormond-street, and gave an analysis of the 39 cases which had been observed at that hospital since 1897, 35 of which had been males. The age at which vomiting had commenced varied; out of 37 cases noted four had commenced at birth, three at one week, nine at two weeks, 11 at three weeks, five at four weeks, two at five weeks, two at six weeks, and one at eight weeks of age. These and other facts threw doubt upon the condition being a congenital defect. Other congenital malformations were notably absent, and the condition did not recur in other members of the same family. Hypertrophy of the pylorus and gastric peristalsis had been detected in all Dr. Voelcker's cases. In regard to the pathology it had been suggested that such cases consisted of a pyloric spasm caused by excess of hydrochloric acid, and Dr. Voelcker was of opinion that the pyloric lesion was secondary to some alteration in the gastric secretion. Out of 39 hospital cases 34 had died. Five of Dr. Voelcker's seven cases had been operated upon, all of whom had died. He attributed the recovery of the other two to lavage and diet. He did not think surgical intervention of any form was advisable.

Mr. F. F. BURGHARD read a paper on the Surgical Treatment of Congenital Pyloric Stenosis, based upon 16 cases that had come under his own care. Five years ago operative

treatment was strongly advocated but of late professional opinion had undergone considerable change. His opinion was that only in a small proportion of cases was operation indicated. He pointed out that the chief difficulty at present was to know in what proportion of cases medical treatment alone might be expected to suffice. Whereas in former years most of the cases came under the surgeon's hands at an early date, the tendency at present was to delay operation as long as possible in the hope that medical measures alone would succeed. This hope was justified in a certain number of cases and the debate would probably do much practical good by enabling surgeons to form some idea of results that were likely to follow medical treatment alone, as hitherto no extended experience had been published. Dealing with the question of operative results, 16 cases in all had been operated upon by the same method—namely, dilatation of the pylorus. Of these cases 11 had recovered satisfactorily from the operation, ten remaining well, whilst one case died within three months of the operation from convulsions; the operative mortality was, therefore, 31·25 per cent., whilst the total mortality was 37·5 per cent. The chief danger of the operation was shock, which could be minimised by careful preliminary preparation and operating rapidly in a well-warmed room, never less than 70° F.; 25 minutes should be sufficient, ten being occupied in the dilatation. Two accidents that had happened in the series of cases quoted were rupture of the pylorus (in two cases) and wound of the duodenum (in one case). These accidents could be treated by immediate suture and were not necessarily fatal. Dilatation of the pylorus was preferable to pyloroplasty but this last was preferable to gastro-jejunostomy. The chief danger of dilatation was splitting the pylorus and to obviate this the incision into the stomach should not be made too near to the pyloric orifice. No recurrence of symptoms occurred after any of the cases quoted.

Dr. HENRY ASHBY (Manchester) said that he had made necropsies on about 11 cases. He had been struck by the marked hypertrophy, though it rarely caused complete obstruction, but he could not help thinking that the hypertrophy was not the essential cause. There were always a large quantity of mucus and other evidences of gastric catarrh. This condition was probably antenatal and produced an over-action of the sphincter which led to the hypertrophy. It was difficult to make out a hypertrophied pylorus during life but with a little patience the abdominal walls might relax and the pylorus drop down from beneath the liver. All his cases had improved temporarily under lavage and small quantities of thin food such as whey. Only one of his cases had been operated upon and the patient had died 12 days later.

Mr. CLINTON T. DENT agreed that the results of surgical intervention had not been very favourable. Out of about 120 collected cases, including a number of unpublished ones, that had been operated on the mortality was about 50 per cent. Unfortunately, surgeons rarely saw these cases until an advanced stage had been reached. Pyloroplasty or pylorotomy was preferable to gastro-enterostomy; the former certainly restored the functions of the pylorus. He had in his possession a section from the pylorus showing that the hypertrophic condition was most certainly antenatal. Prolonged medical treatment certainly jeopardised the surgeon's treatment.

Dr. G. F. STILL said that he had observed 27 cases. Out of 23 in which the result was known 14 had recovered completely; eight of these had been operated on, five of them having been mild cases which had been passed on directly to the surgeon; the other six had been treated medically, five by lavage and one by dieting only. Of the nine that died three were untreated, three were operated on, and three were treated medically. Thus the results were practically as good by medical as by surgical treatment, but each case must be judged on its own merits, not by statistics. He took exception to Mr. Dent's statement as to the undue severity of the cases sent to the surgeon as compared with those treated medically, and he raised the question as to the later results of operative measures. On the other hand, three or four months' persistent lavage was a serious undertaking.

Mr. G. H. MAKINS had operated on two cases and the patients had both recovered, though one had died later from enteritis.

Dr. EDMUND CAWLEY thought that these cases could be differentiated into three classes: (1) pure pyloric spasm without evidence of hypertrophy, attended by vomiting of

from the lymphatics of the legs escaped into the bladder. There was no inflammation in the urinary tract and the kidneys were normal. Purulent pericarditis, hypostatic pneumonia, and acute bronchitis were present. This was the fourth published case of a necropsy on a patient with non-tropical chyluria. He took exception to Mr. Dent's statement as to the undue severity of the cases sent to the surgeon as compared with those treated medically, and he raised the question as to the later results of operative measures. On the other hand, three or four months' persistent lavage was a serious undertaking.

Mr. G. H. MAKINS had operated on two cases and the patients had both recovered, though one had died later from enteritis.

Dr. EDMUND CAUTLEY thought that these cases could be differentiated into three classes: (1) pure pyloric spasm without evidence of hypertrophy, attended by vomiting of

found to be ill to obtain medical aid and for this purpose when necessary supplying them with hospital and dispensary tickets. Although it was urged that disinfection should be carried out with discretion, the main preventive measure was to train the patient as regards spitting. For this nothing equalled a month's training and treatment in a sanatorium, irrespectively of whether the case was curable or not. The 25 beds for this purpose and for the longer treatment of early and advanced cases which Brighton possessed at its isolation hospital had doubtless greatly helped the success of its system of voluntary notification of pulmonary tuberculosis. Thus comparing the years of most recent records Brighton had about four cases of pulmonary tuberculosis notified to every two deaths from that disease in the town, while New York had five cases notified to two deaths and Sheffield three cases to two deaths (both having compulsory notification); and Manchester and Liverpool with voluntary notification had three cases notified to two deaths. At the present time nearly 50 per cent. of all cases of the disease notified in Brighton had passed through its borough sanatorium. In conclusion, Dr. News-holme laid stress on the importance of the institutional treatment of advanced cases of pulmonary tuberculosis. At the present time from one-third to one-fifth of the deaths from the disease in some of the great towns occurred in their workhouse infirmaries and these patients lived a large part of a year in these institutions before their death. In his opinion, this unexpected and unforeseen operation of workhouse infirmaries had been during the last 30 years a predominant cause of the decline in the national death-rate from pulmonary tuberculosis and it was in the direction of extension of similar measures, and particularly by removal of all Poor-law conditions from the treatment of the disease, that the most hopeful field for even more rapid decline of the death-rate from pulmonary tuberculosis lay.

Professor G. SIMS WOODHEAD said that he was glad to hear that the two previous speakers, who both spoke as interested in the treatment of individual consumptives, had insisted on the necessity of dealing with and isolating tuberculous patients who might be centres of infection. Whilst agreeing that much might be done in the treatment of the early stages of pulmonary tuberculosis by good food, fresh air, and the like, he thought that the public health side was liable to be somewhat neglected. He had always held that in the clouds of dust which had been raised in the controversy that had raged around Koch's great pronouncement at the British Congress on Tuberculosis one of the most important of the issues laid down in that manifesto had been lost sight of, or, at any rate, had not had assigned to it its proper position. It might be that everyone had agreed so fully on this one point that it had been "taken as read" and also "taken as acted upon," when, as a matter of fact, very little had been done to render consumptives in the later and really infective stages less dangerous as centres of infection to their fellows. Patients who were treated in sanatoriums were trained to limit the distribution of their sputa and to insure its disinfection, but the patient in an advanced stage of the disease was often allowed to disseminate, and to disseminate very widely, dangerous infective material in a way that would be deemed absolutely criminal in the case of typhoid fever or diphtheria. Again, the precautions taken against the spread of leprosy, a far less general and fatal though certainly more repulsive disease, were infinitely more stringent than the most stringent ever adopted against the spread of tuberculosis. Speaking from his own special point of view, he was convinced that the voluntary method of notification was not only a rational but a feasible method and one that, if carried out with tact and a reasonable amount of judgment and good sense, should secure most of the advantages of compulsory notification with but few of its drawbacks. Moreover, should it be found later that compulsory notification was desirable, the experience gained under the voluntary system should prove of enormous value to those who would be responsible for the drawing up and putting into force of the compulsory system. He was deeply grateful to the openers of the discussion for the very clear and forcible lead that they had given to the interested in this very important question.

Dr. S. HUMPHRY expressed the opinion that enough attention was not paid to the question of dealing with the advanced cases of consumption. All their efforts were directed to the care of the early cases and large sums of money were expended on the treatment of this stage of

the disease. Although no doubt there was good reason for this course he thought that amongst the poorer classes the number of cases in which the disease was arrested for any great length of time was comparatively small. Such patients were unable to give up the time which it was necessary to spend in a sanatorium during several successive winters and in the intervals their surroundings and necessary occupations often undid much of the good they had obtained and in the end they joined the ranks of the advanced cases. This was, no doubt, partly due to the very great difficulty of getting hold of the disease in its earliest stage. Dr. Humphry thought that every advanced case which was uncared for was a potent source of infection and was in all probability the source of several early cases and yet very little was being done to deal with them effectively; they were usually excluded from hospitals and sanatoriums and were a source of difficulty in workhouses and infirmaries; they lost heart, discarded the list of hygienic directions given them in their previous ill-health, and ended in distributing the infection in their unhealthy alleys and homes. The public were willing to give their money to prevent children being infected by milk and to erect sanatoriums for the early cases, while the most potent source of infection of all was not provided for. Dr. Humphry would be in favour of the voluntary notification of pulmonary tuberculosis if he thought that the advanced cases could thereby be rendered less dangerous to the community.

Professor HOWARD MARSH said that he had been greatly interested by the papers read by Dr. Forbes and Dr. News-holme. The subject was one of the most important in the whole field of sanitary development at the present time. Indeed, the limitation, and ultimately the total abolition, of tuberculosis in man and the lower animals was an enterprise which might well be regarded as of Imperial concern. Moreover, the means of achieving this great victory over disease were well known; they were, in fact, ready to hand, if only, or whenever, they could be efficiently carried out. The voluntary notification of tuberculosis was surrounded by difficulties which at first sight appeared to be insurmountable. But he was much impressed by the attitude which Dr. News-holme had adopted towards it, and which consisted in travelling warily and most skilfully along the lines of least resistance. So proceeding Dr. News-holme had evidently already made very substantial progress and had shown not only on paper but by practical results that those who went the right way to work could by tact and resource, and by winning the confidence of patients and teaching them how much they would gain, secure voluntary notification in a large proportion of cases. This was, so to say, half the battle, for unquestionably voluntary notification was a most potent agent on the side of those who were struggling to eradicate tuberculosis. For his part he should watch the movement with the greatest interest and, remembering what they had just heard, with full confidence not only that voluntary notification was capable of rendering very valuable service but that it could be worked efficiently and on a scale readily admitting of wide extension.

Mr. F. E. ARTHORPE WEBB stated that he thought much good might be done by the notification of pulmonary tuberculosis. A great point was made of the desirability of discovering early cases, but it was just as important to treat advanced cases hygienically in order to prevent infection of others. He moved the following proposition:—

That in the opinion of the Cambridge Medical Society it is eminently desirable that steps be taken by the local health authority to initiate a system of voluntary notification of phthisis.

This was unanimously carried and a vote of thanks to Dr. News-holme for his paper, proposed by Professor G. R. F. NUTTALL, and carried by acclamation, terminated the proceedings.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF PATHOLOGY. *Exhibition of Specimens*

A MEETING of this section was held on Feb. 15th, Dr. J. F. O'CARROLL, the President, being in the chair. Dr. L. G. GUNN exhibited a specimen taken from a man, aged about 45 years, who had been admitted to hospital with the usual symptoms of Tuberculosis of the Urinary Tract.

from the lymphatics of the legs escaped into the bladder. There was no inflammation in the urinary tract and the kidneys were normal. Purulent pericarditis, hypostatic pneumonia, and acute bronchitis were present. This was the fourth published case of a necropsy on a patient with non-tropical chyluria. There were strong reasons for believing that all cases of chyluria, whether due to filariæ or not, were caused by the same anatomical abnormality—viz., obstruction to the thoracic duct or large abdominal lymphatics, with consequent dilatation of abdominal and pelvic lymphatics and rupture of a dilated lymphatic into the urinary tract. The obstruction in filarial chyluria appeared to be due to a fibrous stenosis of the thoracic duct, secondary to inflammation brought about by the presence of filariæ at some earlier period. The parasites themselves had never been found blocking the thoracic duct. As the obstruction, when once produced, would be permanent it would remain after the filariæ had all died out. Hence cases, such as the present one, in which the patient had been abroad 20 years before the onset of the chyluria, might quite well have been due to an old infection with filariæ which had completely died out, leaving the obstruction in the thoracic duct. Presumably the rupture of a dilated lymphatic into the bladder occurred only in March, 1906. In non-filarial cases the obstruction was probably due to some other parasite, or more frequently to caseous glands or other tumour pressing on the duct from without. Hence the distinction between tropical and non-tropical chyluria was artificial and not warranted by the pathogenesis of the two conditions.

Mr. T. M. HAMELL said that he had made observations on a subject in which chyle came from a chylous fistula. The rate of appearance of fat in the chyle was dependent on the condition of the fat and whether it had a high or low melting point. The fats with a low melting point appeared more rapidly than those with a high melting point. He had never been able to detect dextrose in the chyle. He asked whether by any operation it was possible to connect the part of the thoracic duct below the lesion with that above it.

Dr. HERTZ, in reply, said that he had made no experiments with regard to the rapidity of absorption of the fats with the high or low melting points, but for the ordinary fats of food it took only half an hour before they began to appear in the urine. Exercise increased the lymph flow and the rapidity with which the fat appeared in the urine.

CLINICAL SOCIETY OF LONDON.

The Medical and Surgical Treatment of Congenital Pyloric Stenosis.

A MEETING of this society was held on March 8th, Mr. H. H. OLUTTON, the President, being in the chair.

Dr. G. A. SUTHERLAND read a paper on the Medical Treatment of Congenital Pyloric Stenosis, which will be found at p. 725 in the present issue of THE LANCET.

Dr. A. F. VOELCKER read short abstracts of seven cases of Hypertrophic Pyloric Stenosis in infants who had been under his care at the Hospital for Sick Children, Great Ormond-street, and gave an analysis of the 39 cases which had been observed at that hospital since 1897, 35 of which had been males. The age at which vomiting had commenced varied; out of 37 cases noted four had commenced at birth, three at one week, nine at two weeks, 11 at three weeks, five at four weeks, two at five weeks, two at six weeks, and one at eight weeks of age. These and other facts threw doubt upon the condition being a congenital defect. Other congenital malformations were notably absent, and the condition did not recur in other members of the same family. Hypertrophy of the pylorus and gastric peristalsis had been detected in all Dr. Voelcker's cases. In regard to the pathology it had been suggested that such cases consisted of a pyloric spasm caused by excess of hydrochloric acid, and Dr. Voelcker was of opinion that the pyloric lesion was secondary to some alteration in the gastric secretion. Out of 39 hospital cases 34 had died. Five of Dr. Voelcker's seven cases had been operated upon, all of whom had died. He attributed the recovery of the other two to lavage and diet. He did not think surgical intervention of any form was advisable.

Mr. F. F. BURGHARD read a paper on the Surgical Treatment of Congenital Pyloric Stenosis, based upon 16 cases that had come under his own care. Five years ago operative

treatment was strongly advocated but of late professional opinion had undergone considerable change. His opinion was that only in a small proportion of cases was operation indicated. He pointed out that the chief difficulty at present was to know in what proportion of cases medical treatment alone might be expected to suffice. Whereas in former years most of the cases came under the surgeon's hands at an early date, the tendency at present was to delay operation as long as possible in the hope that medical measures alone would succeed. This hope was justified in a certain number of cases and the debate would probably do much practical good by enabling surgeons to form some idea of results that were likely to follow medical treatment alone, as hitherto no extended experience had been published. Dealing with the question of operative results, 16 cases in all had been operated upon by the same method—namely, dilatation of the pylorus. Of these cases 11 had recovered satisfactorily from the operation, ten remaining well, whilst one case died within three months of the operation from convulsions; the operative mortality was, therefore, 31·25 per cent., whilst the total mortality was 37·5 per cent. The chief danger of the operation was shock, which could be minimised by careful preliminary preparation and operating rapidly in a well-warmed room, never less than 70° F.; 25 minutes should be sufficient, ten being occupied in the dilatation. Two accidents that had happened in the series of cases quoted were rupture of the pylorus (in two cases) and wound of the duodenum (in one case). These accidents could be treated by immediate suture and were not necessarily fatal. Dilatation of the pylorus was preferable to pyloroplasty but this last was preferable to gastro-jejunostomy. The chief danger of dilatation was splitting the pylorus and to obviate this the incision into the stomach should not be made too near to the pyloric orifice. No recurrence of symptoms occurred after any of the cases quoted.

Dr. HENRY ASHBY (Manchester) said that he had made necropsies on about 11 cases. He had been struck by the marked hypertrophy, though it rarely caused complete obstruction, but he could not help thinking that the hypertrophy was not the essential cause. There were always a large quantity of mucus and other evidences of gastric catarrh. This condition was probably antenatal and produced an over-action of the sphincter which led to the hypertrophy. It was difficult to make out a hypertrophied pylorus during life but with a little patience the abdominal walls might relax and the pylorus drop down from beneath the liver. All his cases had improved temporarily under lavage and small quantities of thin food such as whey. Only one of his cases had been operated upon and the patient had died 12 days later.

Mr. CLINTON T. DENT agreed that the results of surgical intervention had not been very favourable. Out of about 120 collected cases, including a number of unpublished ones, that had been operated on the mortality was about 50 per cent. Unfortunately, surgeons rarely saw these cases until an advanced stage had been reached. Pyloroplasty or pylorotomy was preferable to gastro-enterostomy; the former certainly restored the functions of the pylorus. He had in his possession a section from the pylorus showing that the hypertrophic condition was most certainly antenatal. Prolonged medical treatment certainly jeopardised the surgeon's treatment.

Dr. G. F. STILL said that he had observed 27 cases. Out of 23 in which the result was known 14 had recovered completely; eight of these had been operated on, five of them having been mild cases which had been passed on directly to the surgeon; the other six had been treated medically, five by lavage and one by dieting only. Of the nine that died three were untreated, three were operated on, and three were treated medically. Thus the results were practically as good by medical as by surgical treatment, but each case must be judged on its own merits, not by statistics. He took exception to Mr. Dent's statement as to the undue severity of the cases sent to the surgeon as compared with those treated medically, and he raised the question as to the later results of operative measures. On the other hand, three or four months' persistent lavage was a serious undertaking.

Mr. G. H. MAKINS had operated on two cases and the patients had both recovered, though one had died later from enteritis.

Dr. EDMUND CAUTLEY thought that these cases could be differentiated into three classes: (1) pure pyloric spasm without evidence of hypertrophy, attended by vomiting of

As far as could be diagnosed he had a large right kidney, from which it was thought that the pus in the urine was proceeding. The bladder was small, contracted, and tuberculous. A cryoscopic examination led to the conclusion that the patient was on the borderland of insufficiency and the right kidney was thought to be a bag of tuberculous pus. On operating a large kidney was found having a great deal of apparently healthy tissue in it. On exploring the pelvis of the kidney tuberculosis was found to be present. Dr. Gunn presumed that he had been wrong in thinking the other kidney healthy; he therefore did not take the right kidney out. The patient died two days afterwards, and the necropsy showed that the cause of death was extensive miliary tuberculosis affecting the liver, the lung, and the spleen. The left kidney was a tiny structure but perfectly healthy. On account of its smallness, which was apparently congenital, it would by itself alone be functionally inadequate for the maintenance of life. The primary tuberculous focus was a small chronic abscess in the prostate.—Professor E. J. McWEENEY said that the large kidney was a beautiful specimen of compensatory hypertrophy; the other was the smallest he had ever seen which bore no evidence of organic disease.

Dr. A. R. PARSONS showed a Liver affected with Cirrhosis and Carcinoma obtained from a woman, 42 years of age, who had been admitted to hospital in November, 1906, complaining of considerable swelling of the abdomen and also of the legs. The swelling of the abdomen, which had commenced three months previously, had not interfered with her until some six weeks before admission. She gave an ill-defined history of alcoholism; the liver was uniformly enlarged; the spleen was considerably enlarged; there was a history of hæmorrhoids; and the fluid obtained on tapping was clear and non-sanguineous. These symptoms indicated cirrhosis but, on the other hand, the rapid emaciation and short history of the case were supposed to suggest malignant disease. No primary focus could be palpated in any part of the abdomen. On opening the abdomen after death the liver was found to be enlarged considerably and affected with malignant disease. Advanced cirrhosis of the liver, usually attributed to alcoholism, was also present. There was no evidence whatever of primary malignant growth in the stomach, pancreas, intestines, uterus, and ovaries, and the naked-eye appearance of the liver and the microscopic sections showed that the growth was primary in the liver. There were secondary nodules in the lung. The case represented an unusual combination of primary malignant disease and advanced cirrhosis of the liver.

Dr. PARSONS also showed specimens obtained from a case of Lymphatism. The patient was a boy, aged seven months; he was perfectly well until the day before his admission to hospital and he died about one and a half hours after admission. The thymus gland was enormously enlarged and covered quite a large portion of the heart. In reference to this Dr. Parsons said that in 1892 he had met with several cases of sudden death in children from one to five years of age, in which the only abnormal post-mortem appearance was great enlargement of the adenoid tissue of the intestines. Dr. George Peacocke had described two or three cases which were identical with his own cases and referred to a paper by Dr. Ewing of New York who, following Paltauf, called the condition lymphatism. The cases were characterised by sudden death, frequently, but not always, preceded by convulsions; and the necropsy revealed nothing sufficient to account for death. Dr. Peacocke observed in his cases extreme enlargement of the thymus gland.—Dr. PEACOCKE said that he had never found any enlargement of the external lymphatic glands. He was sure that a great many cases occurred which were ascribed to convulsions.

Professor ARTHUR H. WHITE exhibited organisms obtained from cases of cerebro-spinal meningitis. From the first case reported he had made direct cultivations from spinal fluid obtained aseptically by lumbar puncture in broth, human blood serum, glycerine agar, and litmus milk. The broth next day was barely clouded; tiny discrete grey colonies developed on the serum; the glycerine agar remained sterile. Subsequent examination showed these growths to be pure cultures of a diplococcus, sometimes seen in tetrad form, staining irregularly with simple stains like Löffler's blue and negative to Gram's stain. Microscopic examination of the cerebro-spinal fluid showed very many pus corpuscles and numerous organisms seen mainly as diplococci but there

were many tetrads and a few short chains. A considerable number of these organisms were inside the pus cells. Some of them appeared to have capsules and, like those in the cultures, all were decolourised by Gram's method. He continued the inoculation of further cultures to the fifth generation, which was still alive. The fourth and fifth generations had grown very well on ordinary agar, although the original inoculation on the glycerine agar was without result. He had inoculated animals with negative results. The same organism in pure culture was obtained from later cases of the disease, but a smaller number of pus cells and fewer organisms were present, although the cases were more severe clinically. The diplococcus now exhibited had many of the characters of the organism described by Weichselbaum under the name of diplococcus intracellularis meningitidis, but apparently differed from it in having a capsule and in forming short chains. He was not quite satisfied that the organism was a distinct entity, but inclined rather to the opinion that it was a modified pneumococcus.—Professor McWEENEY said that he had observed two cases of Meningitis within the last few days in the Children's Hospital, Temple-street, Dublin. A necropsy was obtained in one of them and revealed the tuberculous form, limited to the cerebral pia-arachnoid. From this numerous tubercle bacilli were obtained in smear preparations. In the other case, which was regarded by Dr. D. J. Farnan as typical cerebro-spinal meningitis, there was no necropsy, but he had examined about five cubic centimetres of fluid obtained from the child (aged three years) by lumbar puncture. The microscopic result was negative, but he had succeeded in growing from it, as the only organism present, a Gram-staining diplococcus tending to form tetrads and growing well in the form of small whitish colonies on ordinary agar, serum agar, and blood agar. He felt sure that this could not be the organism described by Weichselbaum and found by Professor White.

SECTION OF SURGERY.

Frontal Sinusitis.

A meeting of this section was held on Feb. 22nd, Mr. H. R. SWANZY, the President, being in the chair.

Mr. ROBERT H. WOODS exhibited three cases of Frontal Sinusitis subsequently to operation. The operative procedure was as follows. An incision was carried from within outwards along the line of the eyebrow and the frontal sinus was laid open by means of a small trephine, the aperture being subsequently enlarged by means of gouge forceps. The diseased mucous membrane lining the sinus and its recesses was thoroughly removed with a curette. The entire anterior wall of the sinus was not removed, as was generally recommended in the text-books, in order that the scalp might recede and adhere to the posterior sinus wall, because, in his opinion, this step was unnecessary. Obliteration of the cavity could be brought about after removal of the mucous membrane by the growth of granulation tissue from its bony walls.—Mr. P. DEMPSEY alluded to the difficulty in the complete eradication of sinus infection. He said that nothing was easier than to alleviate the discharge and nothing was more difficult than to get it to cease altogether.

The report of the meeting of the Section of State Medicine published in THE LANCET of March 2nd, pp. 591 and 592, contains the full text of a resolution relative to the Poor-law medical service in Ireland adopted by the section. It is now announced that this resolution has been adopted by the General Council of the Royal Academy of Medicine in Ireland.

FORFARSHIRE MEDICAL ASSOCIATION.—A meeting of this society was held on March 7th, Mr. David M. Greig, Vice-President, being in the chair.—Dr. G. A. Pirie exhibited X Ray Photographs of Incipient and Advanced Pulmonary Tuberculosis, Hip-joint Disease, and several Injuries to Joints. He also showed a patient who had recovered from lupus of the face of many years' standing, after repeated application of the x rays.—Mr. Greig exhibited and explained Greville Anderson's Screws and Clamps for the more perfect securing of the ends of ununited fractures in the long bones.—Professor Alexander M. Stalker read a note on Palsus Bistieriens. The case was one of aortic stenosis and a striking clinical feature was the diastolic murmur, which was long, rasping, and squeaking in character, indicating great difficulty in the flow of blood from the ventricle and also in the backward flow of blood

As far as could be diagnosed he had a large right kidney, from which it was thought that the pus in the urine was proceeding. The bladder was small, contracted, and tuberculous. A cryoscopic examination led to the conclusion that the patient was on the borderland of insufficiency and the right kidney was thought to be a bag of tuberculous pus. On operating a large kidney was found having a great deal of apparently healthy tissue in it. On exploring the pelvis of the kidney tuberculosis was found to be present. The same organism in pure culture was obtained from later cases of the disease, but a smaller number of pus cells and fewer organisms were present, although the cases were more severe clinically. The diplococcus now exhibited had many of the characters of the organism described by Weichselbaum under the name of *diplococcus intracellularis meningitidis*, but apparently differed from it in having a capsule and in forming short chains. He was not quite satisfied that the organism was a distinct entity, but inclined rather to the opinion that it was a modified pneumococcus.—Professor McWEENEY said that he had observed two cases of Meningitis within the last few days in the Children's Hospital, Temple-street, Dublin. A necropsy was obtained in one of them and revealed the tuberculous form, limited to the cerebral pia-arachnoid. From this numerous tubercle bacilli were obtained in smear preparations. In the other case, which was regarded by Dr. D. J. Farnan as typical cerebro-spinal meningitis, there was no necropsy, but he had examined about five cubic centimetres of fluid obtained from the child (aged three years) by lumbar puncture. The microscopic result was negative, but he had succeeded in growing from it, as the only organism present, a Gram-staining diplococcus tending to form tetrads and growing well in the form of small whitish colonies on ordinary agar, serum agar, and blood agar. He felt sure that this could not be the organism described by Weichselbaum and found by Professor White.

SECTION OF SURGERY.

Frontal Sinusitis.

A meeting of this section was held on Feb. 22nd, Mr. H. R. SWANZ, the President, being in the chair.

Mr. ROBERT H. WOODS exhibited three cases of Frontal Sinusitis subsequently to operation. The operative procedure was as follows. An incision was carried from within outwards along the line of the eyebrow and the frontal sinus was laid open by means of a small trephine, the aperture being subsequently enlarged by means of gouge forceps. The diseased mucous membrane lining the sinus and its recesses was thoroughly removed with a curette. The entire anterior wall of the sinus was not removed, as was generally recommended in the text-books, in order that the scalp might recede and adhere to the posterior sinus wall, because, in his opinion, this step was unnecessary. Obliteration of the cavity could be brought about after removal of the mucous membrane by the growth of granulation tissue from its bony walls.—Mr. P. DEMPSEY alluded to the difficulty in the complete eradication of sinus infection. He said that nothing was easier than to alleviate the discharge and nothing was more difficult than to get it to cease altogether.

The report of the meeting of the Section of State Medicine published in THE LANCET of March 2nd, pp. 591 and 592, contains the full text of a resolution relative to the Poor-law medical service in Ireland adopted by the section. It is now announced that this resolution has been adopted by the General Council of the Royal Academy of Medicine in Ireland.

FORFARSHIRE MEDICAL ASSOCIATION.—A meeting of this society was held on March 7th, Mr. David M. Greig, Vice-President, being in the chair.—Dr. G. A. Pirie exhibited X Ray Photographs of Incipient and Advanced Pulmonary Tuberculosis, Hip-joint Disease, and several Injuries to Joints. He also showed a patient who had recovered from lupus of the face of many years' standing, after repeated application of the x rays.—Mr. Greig exhibited and explained Greville Anderson's Screws and Clamps for the more perfect securing of the ends of ununited fractures in the long bones.—Professor Alexander M. Stalker read a note on Pulsus Bisferiens. The case was one of aortic stenosis and a striking clinical feature was the diastolic murmur, which was long, rasping, and squeaking in character, indicating great difficulty in the flow of blood from the ventricle and also in the backward flow. He stated

As far as could be diagnosed he had a large right kidney, from which it was thought that the pus in the urine was proceeding. The bladder was small, contracted, and tuberculous. A cryoscopic examination led to the conclusion that the patient was on the borderland of insufficiency and the right kidney was thought to be a bag of tuberculous pus. On operating a large kidney was found having a great deal of apparently healthy tissue in it. On exploring the pelvis of the kidney tuberculosis was found to be present. Dr. Gunn presumed that he had been wrong in thinking the other kidney healthy; he therefore did not take the right kidney out. The patient died two days afterwards, and the necropsy showed that the cause of death was extensive military tuberculosis affecting the liver, the lung, and the spleen. The left kidney was a tiny structure but perfectly healthy. On account of its smallness, which was apparently congenital, it would by itself alone be functionally inadequate for the maintenance of life. The primary tuberculous focus was a small chronic abscess in the prostate.—Professor E. J. McWENNEY said that the large kidney was a beautiful specimen of compensatory hypertrophy; the other was the smallest he had ever seen which bore no evidence of organic disease.

Dr. A. R. PARSONS showed a Liver affected with Cirrhosis and Carcinoma obtained from a woman, 42 years of age, who had been admitted to hospital in November, 1906, complaining of considerable swelling of the abdomen and also of the legs. The swelling of the abdomen, which had commenced three months previously, had not interfered with her until some six weeks before admission. She gave an ill-defined history of alcoholism; the liver was uniformly enlarged; the spleen was considerably enlarged; there was a history of hæmorrhoids; and the fluid obtained on tapping was clear and non-sanguineous. These symptoms indicated cirrhosis but, on the other hand, the rapid emaciation and short history of the case were supposed to suggest malignant disease. No primary focus could be palpated in any part of the abdomen. On opening the abdomen after death the liver was found to be enlarged considerably and affected with malignant disease. Advanced cirrhosis of the liver, usually attributed to alcoholism, was also present. There was no evidence whatever of primary malignant growth in the stomach, pancreas, intestines, uterus, and ovaries, and the naked-eye appearance of the liver and the microscopic sections showed that the growth was primary in the liver. There were secondary nodules in the lung. The case represented an unusual combination of primary malignant disease and advanced cirrhosis of the liver.

Dr. PARSONS also showed specimens obtained from a case of Lymphatism. The patient was a boy, aged seven months; he was perfectly well until the day before his admission to hospital and he died about one and a half hours after admission. The thymus gland was enormously enlarged and covered quite a large portion of the heart. In reference to this Dr. Parsons said that in 1892 he had met with several cases of sudden death in children from one to five years of age, in which the only abnormal post-mortem appearance was great enlargement of the adenoid tissue of the intestines. Dr. George Peacocke had described two or three cases which were identical with his own cases and referred to a paper by Dr. Ewing of New York who, following Paltauf, called the condition lymphatism. The cases were characterised by sudden death, frequently, but not always, preceded by convulsions; and the necropsy revealed nothing sufficient to account for death. Dr. Peacocke observed in his cases extreme enlargement of the thymus gland.—Dr. PEACOCKE said that he had never found any enlargement of the external lymphatic glands. He was sure that a great many cases occurred which were ascribed to convulsions.

Professor ARTHUR H. WHITE exhibited organisms obtained from cases of cerebro-spinal meningitis. From the first case reported he had made direct cultivations from spinal fluid obtained aseptically by lumbar puncture in broth, human blood serum, glycerine agar, and litmus milk. The broth next day was barely clouded; tiny discrete grey colonies developed on the serum; the glycerine agar remained sterile. Subsequent examination showed these growths to be pure cultures of a diplococcus, sometimes seen in tetrad form, staining irregularly with simple stains like Löffler's blue and negative to Gram's stain. Microscopic examination of the cerebro-spinal fluid showed very many pus corpuscles and numerous organisms seen mainly as diplococci but there

were many tetrads and a few short chains. A considerable number of these organisms were inside the pus cells. Some of them appeared to have capsules and, like those in the cultures, all were decolourised by Gram's method. He continued the inoculation of further cultures to the fifth generation, which was still alive. The fourth and fifth generations had grown very well on ordinary agar, although the original inoculation on the glycerine agar was without result. He had inoculated animals with negative results. The same organism in pure culture was obtained from later cases of the disease, but a smaller number of pus cells and fewer organisms were present, although the cases were more severe clinically. The diplococcus now exhibited had many of the characters of the organism described by Weichselbaum under the name of diplococcus intracellularis meningitidis, but apparently differed from it in having a capsule and in forming short chains. He was not quite satisfied that the organism was a distinct entity, but inclined rather to the opinion that it was a modified pneumococcus.—Professor McWENNEY said that he had observed two cases of Meningitis within the last few days in the Children's Hospital, Temple-street, Dublin. A necropsy was obtained in one of them and revealed the tuberculous form, limited to the cerebral pia-arachnoid. From this numerous tubercle bacilli were obtained in smear preparations. In the other case, which was regarded by Dr. D. J. Farnan as typical cerebro-spinal meningitis, there was no necropsy, but he had examined about five cubic centimetres of fluid obtained from the child (aged three years) by lumbar puncture. The microscopic result was negative, but he had succeeded in growing from it, as the only organism present, a Gram-staining diplococcus tending to form tetrads and growing well in the form of small whitish colonies on ordinary agar, serum agar, and blood agar. He felt sure that this could not be the organism described by Weichselbaum and found by Professor White.

SECTION OF SURGERY.

Frontal Sinusitis.

A meeting of this section was held on Feb. 22nd, Mr. H. R. SWANZY, the President, being in the chair.

Mr. ROBERT H. WOODS exhibited three cases of Frontal Sinusitis subsequently to operation. The operative procedure was as follows. An incision was carried from within outwards along the line of the eyebrow and the frontal sinus was laid open by means of a small trephine, the aperture being subsequently enlarged by means of gouge forceps. The diseased mucous membrane lining the sinus and its recesses was thoroughly removed with a curette. The entire anterior wall of the sinus was not removed, as was generally recommended in the text-books, in order that the scalp might recede and adhere to the posterior sinus wall, because, in his opinion, this step was unnecessary. Obliteration of the cavity could be brought about after removal of the mucous membrane by the growth of granulation tissue from its bony walls.—Mr. P. It is now announced that this resolution has been adopted by the General Council of the Royal Academy of Medicine in Ireland.

FORFARSHIRE MEDICAL ASSOCIATION.—A meeting of this society was held on March 7th, Mr. David M. Grelg, Vice-President, being in the chair.—Dr. G. A. Pirie exhibited X Ray Photographs of Incipient and Advanced Pulmonary Tuberculosis, Hip-joint Disease, and several Injuries to Joints. He also showed a patient who had recovered from lupus of the face of many years' standing, after repeated application of the x rays.—Mr. Grelg exhibited and explained Greville Anderson's Screws and Clamps and explained the more perfect securing of the ends of unfractured fractures in the long bones.—Professor Alexander M. Stalker read a note on Palsus Bisferiens. The case was one of aortic stenosis and a striking clinical feature was the diastolic murmur, which was long, rasping, and squeaking in character, indicating great difficulty in the flow of blood from the ventricle and also in the backward flow. He stated

that some authorities had suggested that the condition shown in tracings of pulsus bisferiens was an artificial one due to some instrumental defect, the sharp needle-like apices of the tracing indicating this. The tracing of the pulse in his case showed a split wave, but it was not due to any defect of the instrument, for a double impact could be most distinctly felt by the finger in both radial pulses. Why pulsus bisferiens should be associated with aortic stenosis he was not prepared to explain, but he was inclined to agree with Dr. Graham Steell's opinion that it was caused by a difference between the rate of the blood flow in the aorta and at the periphery whereby a double wave was produced in the radial pulse.—Dr. R. O. Buist read a note on the Application of Midwifery Forceps. His method was as follows. The patient being under an anæsthetic, in the left lateral position, and the operator's hands and the forceps being previously disinfected, the upper labium was raised with the right hand covered by a swab of wool soaked in lysol solution and four fingers of the left hand were passed into the vagina up to the head and the dorsum was turned towards the hollow of the sacrum. The left blade taken in the right hand was passed along the palm of the left hand and guided into position by the fingers, the handle was raised, and when in proper position it was pushed back towards the perineum and behind the left hand, where it was retained and supported in position by the wrist; the right blade was then introduced in the usual way and the blades were locked. The advantages of this method were, that only one hand was introduced into the vagina and thus the sources of possible infection were reduced and the right hand was available for the introduction of both blades, for the administration of more chloroform, if necessary, or for any other purpose. It was also easy of application and could be managed without assistance.—Dr. William E. Foggie read a paper on three cases of Cerebro-spinal Meningitis. The first patient was a boy, aged five and a half years, of previous good health, who was attacked with headache, sickness, and vomiting which did not yield to ordinary treatment but were followed by great prostration. There was slight feverishness, the pulse was slow and irregular, there was stiffness of the neck and the right arm, and Kernig's symptom was present. The knee-jerks were absent. All the other systems were normal. There were no spots. After seven days' illness he passed into complete unconsciousness, ending in death on the sixteenth day of the illness. Lumbar puncture was performed the day before death. The fluid was clear like water and flowed in a constant slow stream; it showed marked leucocytosis and yielded a pure culture of diplococcus meningitidis intracellularis but no evidence of tubercle. The second patient was a delicate rickety girl, six months old, residing in the same street as the boy. She became ill with signs of gastrointestinal catarrh, followed by stiffness in the neck and back, rigidity in the arms, and speedy unconsciousness. Her temperature was raised, her pulse was rapid and irregular, she had indications of broncho-pneumonia, and her knee-jerks were increased. She showed symmetrical groups of hemorrhagic spots, blue in colour over the pectoral muscles, in areas of the size of a penny, occurring also on the forearms and the back of the elbows. Lumbar puncture yielded slightly blood-stained fluid which contained the diplococcus meningitidis intracellularis. Death took place five days after the onset of the symptoms. The third patient was a boy, aged two years, who two days previous to being seen had fallen and bruised his face. He afterwards became drowsy and then comatose; there was no vomiting, but his mother thought that he had difficulty in swallowing. His temperature was 103° F. and his pulse was 140 per minute and irregular. The right pupil was dilated and did not react; the left one was contracted with well-marked light reflex; the left one strabismic in the left eye. There were no retraction of the head and no stiffness, the limbs being quite flaccid. He died on the fifth day. At the necropsy all the veins in the head were found to be greatly distended with blood; there was slight flattening of the cerebral convolutions and the ventricles were moderately distended with fluid. A soft yellowish-green exudation had formed over the posterior and middle aspect of the brain; it was most marked over the pons and medulla, and spread down both surfaces of the pons to the termination. No tubercles were visible. There was a considerable quantity of turbid, watery fluid in the spinal theca. All the other organs were normal and there was no indication of tubercle anywhere. The fluid contained the pneumococcus of Fraenkel. Dr. Foggie said that the clinical

features of the three cases supported the diagnosis of cerebro-spinal meningitis; it was, however, essential to confirm the diagnosis in such cases by lumbar puncture. Microscopic specimens of normal cerebro-spinal fluid, leucocytosis, Diplococci meningitidis, and pneumococci were exhibited.—In the discussion Professor Stalker expressed his doubt as to the correct diagnosis of many of the early cases in Glasgow, pointing out that since the epidemic commenced the deaths from tuberculous meningitis had decreased in number.

ULSTER MEDICAL SOCIETY.—A meeting of this society was held in Belfast on Feb. 28th, Dr. D. P. Gaussen, the President, being in the chair.—Mr. A. Fullerton read a paper on the Examination of the Urethra and Bladder by the Electric Light. The paper was based on a year's work and included notes of a number of urethroscopies, 111 cases in which the cystoscope was used and 42 cases in which the ureters were catheterised. The urethroscopes which were found most convenient were those of Fenwick and Wyndham Powell. The inflating apparatus was found to be a most valuable addition to the instrument. A case which well illustrated the use of the urethroscope for diagnosis and operative procedure was that of a patient who had violent hæmorrhage from the urethra. The urethroscope showed several papillomata two and a half inches from the meatus. These were removed through a large cannula with complete relief of the symptoms. The cystoscopies were divided into four groups: (1) those in patients whose only or chief symptom was hæmaturia; (2) those in which pyuria was the chief symptom; (3) those who complained chiefly of frequency of micturition; and (4) those who had a combination of symptoms, such as pain, frequency, and blood or pus or both. It was pointed out under (1) that the difficulties of diagnosis in hæmaturia were very considerably reduced by the use of the cystoscope and there was also mentioned the necessity in some instances of using in addition the catheterising cystoscope. In a case of polycystic disease of the right and probably also of the left kidney blood-stained urine was obtained by catheter from the right side and albuminous urine (both of low specific gravity) from the left. In the forlorn hope of saving the patient from death from hæmorrhage the right kidney was removed by the surgeon in charge of the case. The bleeding ceased but the opposite kidney was insufficient and the patient died. The sections of the kidney would appear to support the view that the cysts were formed by dilatation of the tubules. In a second case blood-stained urine was obtained from both ureters by catheter. The specimens contained numerous casts. The rarity of bilateral hæmaturia in these symptomless cases was pointed out. In a third case the hæmorrhage was found to come from the left ureter and a small spicule of oxalate of lime was removed from the kidney on that side, thereby curing a hæmaturia which had lasted for four years. This patient, like the last, had no localising symptoms. Under heading No. 2 a number of cases of pyuria were described in which it would have been impossible without the catheterising cystoscope accurately to have located the mischief. In one case the pus was discovered in routine examination by the medical attendant and tubercle bacilli were found in the urine. The urethral catheter drew off purulent urine from the right kidney, though no pain or swelling was present in that region. Under heading No. 3 cases of enlarged prostate were mentioned in which no residual urine or enlargement per rectum could be discovered. The cystoscope showed, however, intravesical projections, the cause undoubtedly of irritability and frequency. A small prostate weighing four drachms, removed by the suprapubic route, was shown, in which a polypoid projection occupied the prostatic urethra and caused much irritability. It contained one large and a number of small stones in its substance. In a case of frequency about a score of small, round, yellowish nodules were found on the posterior wall of the bladder with no other sign of disease. It was thought these might possibly have been tubercles, although it was pointed out that tubercle in this form was rare. Group 4 included a large number of cases and examples were given to show how easily a mistaken diagnosis might be arrived at without visual examination of the bladder. Under this heading cases of cystitis, tubercle, ulcer, stone, benign papilloma, malignant disease, and bilharzia hæmaturia were quoted. In one case an acute cystitis occurred with sloughing of a large area on the left posterior superior wall. The slough separated, leaving the

As far as could be diagnosed he had a large right kidney, from which it was thought that the pus in the urine was proceeding. The bladder was small, contracted, and tuberculous. A cryoscopic examination led to the conclusion that the patient was on the borderland of insufficiency and the right kidney was thought to be a bag of tuberculous pus. On operating a large kidney was found having a great deal of apparently healthy tissue in it. On exploring the pelvis of the kidney tuberculosis was found to be present. Dr. Gunn presumed that he had been wrong in thinking the other kidney healthy; he therefore did not take the right kidney out. The patient died two days afterwards, and the necropsy showed that the cause of death was extensive miliary tuberculosis affecting the liver, the lung, and the spleen. The left kidney was a tiny structure but perfectly healthy. On account of its smallness, which was apparently congenital, it would by itself alone be functionally inadequate for the maintenance of life. The primary tuberculous focus was a small chronic abscess in the prostate.—Professor E. J. McWEENEY said that the large kidney was a beautiful specimen of compensatory hypertrophy; the other was the smallest he had ever seen which bore no evidence of organic disease.

Dr. A. R. PARSONS showed a Liver affected with Cirrhosis and Carcinoma obtained from a woman, 42 years of age, who had been admitted to hospital in November, 1906, complaining of considerable swelling of the abdomen and also of the legs. The swelling of the abdomen, which had commenced three months previously, had not interfered with her until some six weeks before admission. She gave an ill-defined history of alcoholism; the liver was uniformly enlarged; the spleen was considerably enlarged; there was a history of hemorrhoids; and the fluid obtained on tapping was clear and non-sanguineous. These symptoms indicated cirrhosis but, on the other hand, the rapid emaciation and short history of the case were supposed to suggest malignant disease. No primary focus could be palpated in any part of the abdomen. On opening the abdomen after death the liver was found to be enlarged considerably and affected with malignant disease. Advanced cirrhosis of the liver, usually attributed to alcoholism, was also present. There was no evidence whatever of primary malignant growth in the stomach, pancreas, intestines, uterus, and ovaries, and the naked-eye appearance of the liver and the microscopic sections showed that the growth was primary in the liver. There were secondary nodules in the lung. The case represented an unusual combination of primary malignant disease and advanced cirrhosis of the liver.

Dr. PARSONS also showed specimens obtained from a case of Lymphatism. The patient was a boy, aged seven months; he was perfectly well until the day before his admission to hospital and he died about one and a half hours after admission. The thymus gland was enormously enlarged and covered quite a large portion of the heart. In reference to this Dr. Parsons said that in 1892 he had met with several cases of sudden death in children from one to five years of age, in which the only abnormal post-mortem appearance was great enlargement of the adenoid tissue of the intestines. Dr. George Peacocke had described two or three cases which were identical with his own cases and referred to a paper by Dr. Ewing of New York who, following Paltau, called the condition lymphatism. The cases were characterised by sudden death, frequently, but not always, preceded by convulsions; and the necropsy revealed nothing sufficient to account for death. Dr. Peacocke observed in his cases extreme enlargement of the thymus gland.—Dr. PEACOCKE said that he had never found any enlargement of the external lymphatic glands. He was sure that a great many cases occurred which were ascribed to convulsions.

Professor ARTHUR H. WHITE exhibited organisms obtained from cases of cerebro-spinal meningitis. From the first case reported he had made direct cultivations from spinal fluid obtained aseptically by lumbar puncture in broth, human blood serum, glycerine agar, and litmus milk. The broth next day was barely clouded; tiny discrete grey colonies developed on the serum; the glycerine agar remained sterile. Subsequent examination showed these growths to be pure cultures of a diplococcus, sometimes seen in tetrad form, staining irregularly with simple stains like Löffler's blue and negative to Gram's stain. Microscopic examination of the cerebro-spinal fluid showed very many pus corpuscles and numerous organisms seen mainly as diplococci but there

were many tetrads and a few short chains. A considerable number of these organisms were inside the pus cells. Some of them appeared to have capsules and, like those in the cultures, all were decolourised by Gram's method. He continued the inoculation of further cultures to the fifth generation, which was still alive. The fourth and fifth generations had grown very well on ordinary agar, although the original inoculation on the glycerine agar was without result. He had inoculated animals with negative results. The same organism in pure culture was obtained from later cases of the disease, but a smaller number of pus cells and fewer organisms were present, although the cases were more severe clinically. The diplococcus now exhibited had many of the characters of the organism described by Weichselbaum under the name of diplococcus intracellularis meningitidis, but apparently differed from it in having a capsule and in forming short chains. He was not quite satisfied that the organism was a distinct entity, but inclined rather to the opinion that it was a modified pneumococcus.—Professor McWEENEY said that he had observed two cases of Meningitis within the last few days in the Children's Hospital, Temple-street, Dublin. A necropsy was obtained in one of them and revealed the tuberculous form, limited to the cerebral pia-arachnoid. From this numerous tubercle bacilli were obtained in smear preparations. In the other case, which was regarded by Dr. D. J. Farnan as typical cerebro-spinal meningitis, there was no necropsy, but he had examined about five cubic centimetres of fluid obtained from the child (aged three years) by lumbar puncture. The microscopic result was negative, but he had succeeded in growing from it, as the only organism present, a Gram-staining diplococcus tending to form tetrads and growing well in the form of small whitish colonies on ordinary agar, serum agar, and blood agar. He felt sure that this could not be the organism described by Weichselbaum and found by Professor White.

SECTION OF SURGERY.

Frontal Sinusitis.

A meeting of this section was held on Feb. 22nd, Mr. H. R. SWANZY, the President, being in the chair.

Mr. ROBERT H. WOODS exhibited three cases of Frontal Sinusitis subsequently to operation. The operative procedure was as follows. An incision was carried from within outwards along the line of the eyebrow and the frontal sinus was laid open by means of a small trephine, the aperture being subsequently enlarged by means of gouge forceps. The diseased mucous membrane lining the sinus and its recesses was thoroughly removed with a curette. The entire anterior wall of the sinus was not removed, as was generally recommended in the text-books, in order that the scalp might recede and adhere to the posterior sinus wall, because, in his opinion, this step was unnecessary. Obliteration of the cavity could be brought about after removal of the mucous membrane by the growth of granulation tissue from its bony walls.—Mr. P. DEMPSEY alluded to the difficulty in the complete eradication of sinus infection. He said that nothing was easier than to alleviate the discharge and nothing was more difficult than to get it to cease altogether.

The report of the meeting of the Section of State Medicine published in THE LANCET of March 2nd, pp. 591 and 592, contains the full text of a resolution relative to the Poor-law medical service in Ireland adopted by the section. It is now announced that this resolution has been adopted by the General Council of the Royal Academy of Medicine in Ireland.

FORFARSHIRE MEDICAL ASSOCIATION.—A meeting of this society was held on March 7th, Mr. David M. Greig, Vice-President, being in the chair.—Dr. G. A. Pirie exhibited X Ray Photographs of Incipient and Advanced Pulmonary Tuberculosis, Hip-joint Disease, and several Injuries to Joints. He also showed a patient who had recovered from lupus of the face of many years' standing, after repeated application of the x rays.—Mr. Greig exhibited and explained Greville Anderson's Screws and Olamps and for the more perfect securing of the ends of unfractured fractures in the long bones.—Professor Alexander M. Stalker read a note on Palsus Bisferiens. The case was one of aortic stenosis and a striking clinical feature was the diastolic murmur, which was long, rasping, and squeaking in character, indicating great difficulty in the flow of blood from the ventricle and also in the backward flow. He stated

aged 28 years, who was shown at the meeting and was now in excellent health. Three months ago posterior gastro-jejunostomy was done for cicatrised gastric ulcer with hour-glass contraction of the stomach. After the operation vomiting increased and intestinal obstruction occurred, so that 11 days later an exploratory laparotomy had to be undertaken. The union of stomach and jejunum was found to be perfect, but in its neighbourhood the bowels had become glued together as the result of miliary tuberculosis occurring since the first operation. Separation of the collapsed and adherent coils with division of one band was sufficient to enable peristalsis to be resumed and the patient made a good recovery. There was now no suspicion of peritonitis. The second case was that of a man, aged 59 years, whose symptoms had long suggested ulcerative colitis. He was ultimately found to be the subject of an intussusception five inches long felt per rectum, of which the exciting cause was a papillomatous growth in the sigmoid region. A free excision of 17 inches of bowel as well as a considerable portion of mesocolon was carried out and four months later the resulting artificial anus was closed by a second operation. In the six months since then he had gained a stone in weight and when seen ten months after the first operation was in perfect health.—Dr. Hunter, Mr. A. R. Tweedie, Dr. C. H. Cattle, Mr. T. D. Pryce, Dr. M. Parry-Jones, and Dr. J. Watson discussed the cases.—Mr. A. R. Anderson read a paper on the Resistance of the Urinary Bladder to Infection. He alluded briefly to five cases where there had been a foul prostatic or a rectal or uterine cancer discharging septic material directly into the bladder, saying that it was remarkable how long this state of things might continue without causing actual cystitis. The conditions favouring the occurrence of cystitis were traumatism, congestion, and retention. The last was the most important, as by itself it produced every condition favourable to microbic invasion as well as congestion from the associated straining. The microbes concerned in cystitis were the bacillus coli, the urobacillus, and the pyogenic streptococcus and staphylococcus. Bacteriuria did not necessarily mean cystitis and occurred also in typhoid fever and septic osteomyelitis. The resistance of the mucous membrane was, however, such that the normal bladder was practically invulnerable.—The paper was discussed by Dr. Hunter, Dr. Watson, Dr. Cattle, Dr. F. H. Jacob, and Dr. Parry-Jones, it being pointed out that trophic lesions of the spinal cord greatly favoured the occurrence of cystitis, and Mr. Anderson replied.

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society was held on Feb. 14th, Mr. Russell Oscombe being in the chair.—Dr. R. V. Solly showed a microscopic specimen of a Hair affected with *Microsporon Audouinii*, stained with the modified Gram staining method, where the decolourising was done by aniline oil containing a few drops of strong hydrochloric acid. The method was a very good one, but it took a long time to obtain a permanent specimen. For diagnostic purposes a satisfactory result could be obtained in a much shorter time.—Mr. A. C. Roper showed a specimen of the Femur which had undergone Spontaneous Fracture in the lower third of its shaft owing to tuberculous erosion.—Dr. Solly also showed a case of a child with Double Coloboma Iridis.—Dr. A. W. F. Sayres showed a specimen of Aortic Aneurysm obtained from a patient exhibited before the society nine months previously. The patient exhibited the following especially interesting symptoms: 1. Both radial pulses were absent. 2. He had suffered for four or five years from severe radiating pains around the shoulders, neck, and head, but these had ceased during the latter part of his illness. This probably indicated that the pressure on the nerves had ceased owing to the enlargement of the sac taking place in a different direction. 3. The patient died from dyspnoea, produced by direct pressure on the trachea, three months after being shown before the society. It was interesting to note that there were no symptoms pointing to pressure on the recurrent laryngeal or sympathetic nerves and that there was absence of oedema of the neck. The specimen showed an aneurysm of the size of a small coconut, which involved the ascending, transverse, and part of the descending arch of the thoracic aorta. The upper anterior segment was filled by a firm laminated clot which occupied about two thirds of the entire cavity. The aorta leading from the sac was extremely atheromatous. The innominate artery appeared to be incorporated in the sac and occluded. The right recurrent laryngeal could be traced, coming from beneath the innominate and not around it, but the left was apparently involved

so much in the sac that it could not be discovered and it would appear remarkable that it was not paralysed by stretching. The sternum was much eroded by the forward pressure of the tumour, the bone in places being completely divided. It seemed peculiar that there had been no pressure on the left innominate vein, as the sac had enlarged in a forward and upward direction.—Dr. G. P. D. Hawker read a paper on 100 cases of Appendicular Abscess, the record of which cases he had obtained from the notes of St. Mary's Hospital, London.

DERMATOLOGICAL SOCIETY OF GREAT BRITAIN AND IRELAND.—A meeting of this society was held on Feb. 27th, Dr. Leslie Roberts, the President, being in the chair.—Dr. V. H. Rutherford showed a Case for Diagnosis. The patient was a young man, aged 18 years, with a large area of pigmentation over the right scapular region extending outwards and downwards over the shoulder-joint and back of the arm. The patch was covered with a few fine hairs. A smaller and less marked area was also present upon the back of the left arm. The condition had only been noticed for about one year, no history of a congenital origin being obtainable. No local irritants had been applied and the area did not itch. Microscopically, there was considerable acanthosis of the prickle-cell layer with an increased deposit of pigment. Various suggestions were put forward, among them being that it was really a congenital mole which had been latent for a long period, or that the condition was allied to acanthosis nigricans.—Mr. A. Shillitoe showed a case of Parapsoriasis of Brocq in a girl, aged 16 years, who had suffered from a scaly eruption "as long as she could remember." She had received antisyphilitic treatment without avail. The entire trunk was covered with a fawn-coloured, slightly scaly, non-infiltrated, patchy eruption.—Dr. A. Eddowes exhibited (1) a man, aged 42 years, with severe and extensive Lichen Planus who had three years previously had an acute general dermatitis; and (2) microscopic specimens from a case of Actinomycosis.—Dr. J. H. Stowers showed a little girl, aged eight years, with Multiple Warts of a most unusual type. Nearly all the growths were more or less symmetrical and of widespread distribution and the analogy to Ichthyosis hystrix was in many cases most marked, as some of the projections were conical and surmounted with hairs. No other member of the family had been similarly affected.—Dr. G. Norman Meachen showed a man, aged 67 years, with Syphilitic Lencoderma affecting the root and dorsum of the penis and also the scrotum. The hypogastric region and perineum was the site of a tertiary eruption of three months' duration, the primary affection being 49 years ago.—Dr. F. Meadows Turner exhibited a case of Long-standing Lichen Planus, the oral mucosa being also affected. Several of the papules presented a linear arrangement.—Mr. G. W. Dawson exhibited a young woman the subject of Acute Lupus Erythematosus, affecting the face and the backs of the hands and fingers, of 18 months' duration.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society was held on March 1st, Dr. Leonard P. Mark, the President, being in the chair.—Mr. John R. Lunn read notes of a case of Retroversion of a Gravid Uterus simulating an Extra-uterine Pregnancy.—Dr. F. G. Crookshank read a paper on the Prognosis and Treatment of Diphtheria, based principally on six years' work at the Mortlake isolation hospital. He alluded to the various factors, knowledge of which was necessary to make an accurate forecast of the course of the disease, referring especially to age incidence and the study of associated cases. He discussed in some detail the general treatment of the disease and especially that of cases marked by evident toxæmia. In these cases he recommended the hypodermic injection of erythrine with-chloride of adrenalin and insisted on the advantage of differentiating clinically the cases in which the incidence of the poison was principally on the central nervous system (vagus nucleus), the heart muscle, or the kidneys.

DEATH OF A CENTENARIAN.—The *Times* of March 12th states that Mrs. Hastings Parker, lady of the manor of Swannington, Norfolk, died on March 8th in her 101st year at her residence, Dadwick House, Buxton Lammes, near Norwich. She was the only child of the late Major Charles Radball of Swannington Hall, and she married in 1853 Captain J. R. T. Hastings Parker who died in 1855.

Reviews and Notices of Books.

International Clinics: A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Pediatrics, Obstetrics, Gynecology, Orthopaedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene, &c., by leading Members of the Medical Profession throughout the World. Edited by A. O. J. KELLY, A.M., M.D., Philadelphia, with the collaboration of other medical men. Vol. IV. Sixteenth Series. London and Philadelphia: J. B. Lippincott Company. 1906. Pp. 322.

THIS volume of these well-known clinics opens with an article on Electro-Therapeutics by Dr. J. W. Rhein, of Philadelphia, who first describes in simple language the fundamental laws of electricity, the physics and mechanism of batteries, the qualities of the current generated by each kind of battery, the physiological action of the different batteries, and the method of applying electricity to the human subject both diagnostically and therapeutically. This article will be found to embrace all the main facts of the subject with which it deals. Following this, Dr. J. M. French discusses the Prevention and Treatment of Chronic Nephritis. The author takes a very comprehensive view of the morbid condition in relation to this term, remarking that every advance in the study of its pathological physiology takes us farther away from the kidneys and deeper into the still hidden processes of metabolism. In the prophylaxis of the affection apposite remarks will be found regarding food, alcohol, tobacco, and the hygiene of the skin, and a timely warning is given against the irritation caused by the excessive administration of strychnine, which the author believes is not as yet properly recognised. In the actual treatment the physician should first of all discover the form and the stage of the nephritis, next its cause, and then the extent to which the kidneys can do their work. Each case must be treated individually. Due commendation is paid to a salt-free diet and it is pointed out that the privation of salt must not be carried beyond the necessity of the case. As regards drugs conditions should be met as they arise and one rule is that constipation should never be permitted to occur. Dr. J. D. Steele next discourses on Chronic Constipation, followed by Dr. P. Grosco on Obesity, in whose article we see no mention of the treatment by drinking very hot water in sips which is sometimes useful.

In the section headed Medicine are several interesting articles. For instance, Dr. W. Porter writes on the Care of Tuberculous Subjects. Here we notice that the author does not seem to have much faith in creosote or its substitutes and predicts that in another decade these remedies will be used very little, if at all, internally. Dr. J. E. Squire next writes on Pulmonary Tuberculosis in the Middle Aged and the Aged, an article which will repay perusal. Amongst other lectures in this section we may notice one by Dr. Arthur E. Elliott on Obscure Renal Hæmaturia, under which term he includes a loosely related group of cases which possess two features in common—viz., unilateral renal hæmaturia and an obscure pathology. Klemperer advocates for these cases a purely medical etiology and holds the theory that the hæmorrhage is due to vaso-motor causes, his hypothesis being that there is paralysis of the vaso-constrictor nerves of the kidney resulting in vaso-dilatation and consequent diapedesis of blood elements. Against this theory, however, is the fact that the bleeding has invariably been found to come from one kidney only in all cases in which proper local investigation has been undertaken. The writer of the paper directs attention to unilateral chronic nephritis as a cause. An interesting lecture on Myxædematous Infantilism and Incomplete Myxœdema is contributed by Dr. R. S. Morris who treats of the

subject very fully. Dr. C. Dieulafoy writes on Syphilitic Aortitis and finally the medical section concludes with an interesting *résumé* by Dr. Leon Bernard of the Recent Progress in the Disorders of the Adrenals.

Amongst the surgical papers Dr. G. Ross writes on the Principles of Treatment of Fractures of the Lower Extremities, an article well illustrated by skiagrams; Dr. R. Hibbs on the Treatment of Hip-joint Disease; and Dr. J. Rinehart on Tuberculous Hip-joint Disease. Dr. David Wallace of the Royal Infirmary, Edinburgh, contributes an excellent article on Vesical Tumours, and then the surgical section concludes with the Treatment of Hæmorrhoids by Dr. G. Müller. In this comprehensive article the various methods of treatment by crushing, submucous ligation, Whitehead's operation, excision and suture of the wound, ligature, clamp and cautery, injection and division, are passed under review and the conclusions arrived at as regards the choice of operation are: (1) that a single pile may be excised and the mucous membrane sutured. (2) Several varicose piles are best treated by the clamp and cautery or lacking that equipment by the ligature. Where hæmorrhage has been a pronounced feature hæmorrhoids are best ligated and in all cases of doubt the clamp and cautery should be used.

The remaining portion of the volume contains articles on Obstetrics, Gynecology, Laryngology, and Otology. The present issue fully keeps up the reputation of its forerunners.

Physical Diagnosis. By E. LEFEVRE, M.D. Second edition, revised and enlarged. Illustrated. London: Hodder and Stoughton. 1906. Pp. 479. Price 10s. net.

THE present edition of this book has been enlarged and several fresh illustrations have been added. The plan of the book is good and should commend itself to the student. The first part, dealing with the anatomy of the trunk, contains some excellent diagrams. But while recognising the utility of the division of the abdomen into regions on a scheme familiarised by long use in anatomical works, we doubt if the author's treatment of the thorax by linear division will be of the same value. The student of physical signs, in England at any rate, will have learnt his thoracic anatomy in another way and will not, we think, be inclined to adopt this new style when he comes to the hospital ward and the out-patient room.

The usual rules regarding the examination of a chest are fully set out in Parts II. and III. and we are glad to see that the author lays great stress on the importance of inspection and palpation as aids to a diagnosis, for the student is too much inclined to resort at once to his stethoscope and so misses valuable signs which inspection and palpation, if first thoroughly conducted, would have taught him. Another point emphasised, and rightly so, is the necessity of becoming familiar with the phenomena of normal respiration. The author regards the use of the pleximeter as likely to mislead the student and gives minute instructions for the positions of the patient and examiner in percussion; and though it may be all very good we do not think that such very definite rules can be laid down for the art of percussion; for surely, where the tactile sense of the fingers and the mental reception and interpretation of the sounds produced play so prominent a part, the individuality of the examiner must form a large element. We like the description given of the difference between "dulness" and "flatness."

Under auscultation is a good account of the structure of the different parts of the respiratory tract and the influence which they have on the sounds produced. The graphic records of the physical signs, which are given on pp. 118-119, do not seem to us to be of much value, except to the originator of them, and we feel sure that the student would waste more time in committing them to memory than their

THE LANCET.

LONDON: SATURDAY, MARCH 16, 1907.

The Alleged Growth of Insanity.

ON Dec. 27th, 1906, the *Times* published a long article dealing with the problem of the growth of insanity. Earlier in 1906 the same correspondent had written in that newspaper two articles on the subject, each of which had been followed by letters from medical experts. Dr. DAVID NICOLSON summed up his view of the matter at that time in an excellent letter which appeared in THE LANCET of June 9th, 1906, p. 1635. In this letter he discussed the subject in a thoroughly judicial spirit, and in so far as it seeks to interpret the meaning to be put on the latest statistics of the Commissioners in Lunacy in this matter it was a valuable expression of opinion and will repay reading now, when the newspapers teem with allusions to the alleged growth of insanity.

The writer in the *Times* in his last communication summarised his propositions under six headings, of which the following are abstracts:—

(a) That in the last 60 years the proportion of certified insane persons to the sane population has grown from 1 in 760 in 1844 to 1 in 272 in 1905 and that in addition to this there is a large fringe of "borderland" cases.

(b) That insanity in all cases and in all its forms is probably largely brought about by physical changes "in the blood or in the fluids or tissues of the brain," and that these changes call for complete investigation by "exact methods of chemical and physical research," supplemented by the skill of "highly trained clinical physicians."

(c) That the commonly accepted "causes" of insanity, such as inheritance, &c., are conditions constantly affecting large numbers of people who do not become insane and that no "causation" in the proper sense of the word can be attributed to them. The *vera causa* in every case must be some changed condition of the blood or tissues of such a kind as to produce disturbance of function in the brain cells which are subservient to thought, and also, if sufficiently severe or long continued, to produce degeneration of their structure.

(d) That the common jargon about so-called "psychology," "mind," "mental disease," and so forth, is a mere incubus upon science.

(e) That the organisation of asylums is not calculated either to attract or to encourage young medical men whose tendencies are in the direction of research.

(f) That the insane being secluded from the outside world and from general medical observation have been practically untouched by the general progress of medical science along other lines and that there has been no substantial advance of knowledge with regard either to the causation of insanity, to the recognition of warnings that it may be impending, or to the discovery of means by which it may be prevented or cured.

We propose to criticise some of these propositions briefly, especially as we find them accepted as proved in some of our lay contemporaries. Figures are often very misleading, and there is little doubt that the real increase of insanity is by no means so alarming as the writer in the *Times* and his nervous followers would have us believe; and further, there are well-recognised causes of the increase, which should tend to allay public apprehension. The public have

greater confidence in the treatment that the insane receive and relatives of patients more readily place them under care. Again, many of those infirm and aged persons whose mental failure is rather one of decay than actual disease are now removed to asylums, whereas in former times they were treated in their own homes or in the infirmaries and escaped official notification as insane. We do not consider that Dr. NICOLSON's differentiation between the "actually" insane and the "potentially" insane, which he drew in the letter to which we have already referred, pretends to do more than to afford an explanation of the large increase in the number of pauper or rate-paid lunatics, seeing that there has been practically no increase in the proportionate number of the *private* class of lunatics. For although it is true that there are many of the "potentially" insane in asylums who for the moment might be liberated, nevertheless if this were done the stress of life would soon make them "actually" insane, and therefore it is clear that they are of more value to society if they remain as workers in asylums. The real question that we have to ask ourselves is, What proportion of the "potentially" insane in our pauper asylums ought never to have been sent there from workhouses or elsewhere? And in this relation the influence of the four-shilling capitation grant must necessarily be a serious item for consideration.

We cordially agree that the time has come when the country and the legislature should realise that some endeavour should be made to face the problem of insanity. For, without disputing over misleading statistics, it is certain that much might be accomplished even with the knowledge which we already possess and which is admitted by all authorities. We do not agree with the *Times* correspondent in his sweeping condemnation regarding the progress of psychological medicine, for much real advance has been made. To have banished many of the old ignorant ideas and to have laid a sound foundation for future knowledge is work which is not easily accomplished. Every man believes that he understands and is capable of discussing this problem of insanity but the solution is by no means so simple as some would have us believe. Even the *Times* correspondent, excellent though some of his propositions would seem to be, falls into the grievous error of urging that "psychology" should be banished as "a mere incubus upon science." It is this ignorance of what a normal mind should be that has hampered progress in the past, for of what value is the study of pathology apart from physiology? If the writer in the *Times* refers to arm-chair theorising when he speaks of psychology his criticism to a certain extent might be accepted, nevertheless the fact remains that the normal mind must be understood before we can hope to interpret correctly its indications of disease. In THE LANCET of Dec. 1st, 1906, p. 1625, we urged the importance of providing wards in general hospitals for the treatment of early cases of mental disorder, as this would supply a double want. Such wards would benefit the individual by saving him from a serious breakdown and they would benefit the community by supplying material to physicians and pathologists whose training has especially fitted them for the investigation of disease. Work, and excellent work, is being accomplished by many medical officers to asylums, but the

that the education of the primary schools would be conducted upon the same lines of direct utility for a purpose definitely in view which will evidently govern the work of the great school for which Mr. GODLEE is the spokesman. The students who come there will come with minds in tune, and they will receive just the instruction fitted to prepare them for the duties in life which they intend to discharge. This definite and practical aim is what is so difficult to obtain in the primary schools of the people.

The rulers of University College and of its attached hospital, like those of some other centres of medical education in the metropolis, have determined to surrender the preliminary subjects forming part of that education to the newly constituted University of London and to reserve their own forces for the conduct of the advanced teaching only; that is to say, for the conversion of students of science into practitioners of medicine. As our readers know, we believe that such a separation of the preliminary from the advanced subjects is likely to improve the teaching of both, and, especially perhaps, of the former which after all form the foundation upon which must depend the safety of the superstructure. In the schools as they were until lately organised the preliminary subjects were necessarily committed to teachers in whose ultimate hopes and aspirations they could fill but a subordinate place, and who, in many cases, would look forward with some eagerness to escape from them. In such conditions the consequent want of enthusiasm would sometimes be liable to extend from the teacher to the class, and the studies in question were in some danger of being regarded as impediments to the learning which the student most desired to receive and which the teacher would have been better pleased to impart. The individual schools, moreover, were only in a few instances large enough to afford to the teachers of preliminary subjects a class either sufficiently numerous to be stimulating or sufficiently remunerative to afford strong inducements to exertion. We believe that most of the London medical schools will be well advised to surrender instruction in the preliminary subjects, and it may reasonably be hoped that under a new régime the teachers of such subjects will hold more distinguished positions and will receive larger payments than have hitherto usually fallen to their share, and that a new sense of the importance of their duties will tend to a general enhancement of their dignity and usefulness.

The Martyrs of Science.

WE published last week an obituary notice of the late Dr. ALLAN MACFADYEN, whose valuable life was cut short at the age of 46 years from Malta fever, the infection being contracted during his bacteriological research work. The trite observation that "every pearl has its price" can have no more forcible illustration than those which may be gleaned from the story of scientific progress. Every step that knowledge takes is over the forms of those who have fought and have fallen in order that it may be taken, and there is no advance perhaps in any direction of scientific progress which has not required its pioneer victims to pave the way. There is little glamour about the fate of the silent martyrs offered to the relentless god of

Progress; no rites or ceremonies attend the sacrifices that he demands. Here and there perhaps one of the martyrs of science, by the great results achieved in his lifetime, attracts the attention and the applause of his fellow men. For every such one though there are a hundred quietly following the path of their duty, unregarded, unrewarded, and, save for the little upward step that their toil has helped, to the end unknown. Such workers there are in every branch of scientific endeavour, be it in the factory, the engineering shop, the cable ship, the chemical laboratory, or the hospital ward. No poet devotes his strains to this army, and the ubiquitous orator of the public press is prone to belittle its work. Yet mankind owns no finer heroes than some who have fallen from the ranks of this student army overwhelmed, by the weight of the physical and spiritual obstacles against which they struggled. It is a strange thing that the applause of men greets only those who fight with men. They who battle with the enemies of man, with disease, with accident, with unknown forces and unknown seas and lands, these men must fight and, if necessary, die almost unnoticed by their fellows. The soldier or the sailor, fine though the patriotism may be that animates his breast and glorious the courage that bears him through, owns no such noble purpose as belongs to him who battles on the side of all human kind.

THACKERAY wondered whether men were naturally cowards at heart that they give such admiration to physical bravery over all other qualities; indeed, it leaves the mind puzzled if we seek to understand how it is that spiritual valour has comparatively so little appreciation amongst us. Perhaps the belief that spiritual valour alone supports the army of workers in the battle of scientific progress keeps public sympathy so cool where scientific work is concerned; but if this is so better knowledge of the facts should dissipate the belief. There is no real difference between the risk of death taken in the battlefield and that taken in the laboratory. In each case death is possibly part of the programme, though in one the risk is met in hot blood and the other in cold. And in each case the courage required is moral as well as physical, though in scientific work the moral side is more obvious. It is only the man who has himself felt the need for courage who realises the fortitude of those who labour on when the end seems more and more doubtful, when hope seems faint and ill-supported; and when the help of companions understanding or encouragement is lacking. In such circumstances as these it is spiritual valour that keeps the worker in scientific fields still steadfast to his task. This is the valour that upholds the explorer, the chemist, the bacteriologist, and it is by courage of this kind that these men, unfortunately only too often, are brought to fill a grave that may well be termed a martyr's. The names of some such martyrs will come readily to the minds of our readers, although no roll of honour commemorates them. They gave their lives, often away from their native country, fighting the foes of their countrymen. Those foes were foul diseases and pestilential conditions of life and soil. Thousands of human lives have been saved already by their endeavours, and we look forward confidently to the time when vast countries devastated now by malarial scourges will be

peopled by healthy and prosperous populations. The time must soon come when the conquests of science will cease to rank low beside the martial acquisitions of war. At the present time a town sacked brings more credit to the operator than a huge area redeemed by sanitation in the strife between science and uncontrolled natural forces. Certainly one modern statesman has pointed out the nation's enormous indebtedness to scientific workers in our possessions beyond the seas, but Mr. CHAMBERLAIN'S words were striking because they were so rare. It will be some time before the public, at any rate in this country, learns to appreciate scientific work.

Annotations.

"No quid nimis."

THE NOTIFICATION OF CEREBRO-SPINAL FEVER.

THE notification of epidemic cerebro-spinal meningitis has been introduced into the county of London, as we said last week. The county of London has a population of nearly 5,000,000 and the departure affords an opportunity to the sanitary service of the metropolis of accumulating data and experience on a scale which could not easily be obtained elsewhere in the world. If the medical profession in London coöperates cordially and conscientiously in this experiment with the medical officers of health and if these officers in turn afford to Sir Shirley F. Murphy and his staff every possible assistance in filling up accurately the tables which have been circulated, material progress in our knowledge of this still mysterious malady should be made. Great responsibility will rest with the officers of the London County Council in grouping the somewhat miscellaneous data which will doubtless reach them and upon discrimination in this grouping will depend the value of the data for educational purposes. To the vast majority of medical practitioners in this country cerebro-spinal fever, so far as practical experience goes, is a closed book, and thus reliance will have for the most part to be placed upon diagnosis from book knowledge and by the method of exclusion, together with such assistance as can be afforded by those who have had opportunities of seeing cases of the disease. But, as we are told in the memorandum which has been circulated by Mr. W. H. Power, the medical officer of the Local Government Board, although typical cases may prove easy of diagnosis departures from the type are so common that the malady has at one or another time been mistaken for sunstroke, enteric fever, pneumonia, sore-throat, or influenza. It is in these circumstances that notification may be likely materially to aid diagnosis by bringing to the knowledge of medical officers of health such groupings of anomalous cases as to lead to the suspicion that cerebro-spinal fever may be the disease in question. Furthermore, we are likely by carefully recorded information to ascertain somewhat more definitely whether or not the disease is communicable from person to person and, if so, what is the degree of such infectivity. It will be well in this connexion if a healthy scepticism be observed with regard to the evidence, more especially lest any group of cases evincing apparent infectivity may eventually be proved to be cases not of cerebro-spinal fever but of influenza or enteric fever. If the forms which have been circulated by the London County Council are properly filled up and the number of persons exposed in each invaded home are recorded the combined statistics should afford as much information not only as to the question of infectivity but also as to the fatality-rate and

period of incubation of the disease. Doubtless, too, facilities will be afforded either by the borough councils or the London County Council for the examination, when desirable, of the nasal and oral mucus, as also, in cases where lumbar puncture can be conveniently and safely performed, of the cerebro-spinal fluid. It will be of interest to learn to what extent cases of meningitis other than cerebro-spinal are notified and what at the end of the six months has been the cost of the experiment. The County Council has certainly been well advised to undertake this work and we have no doubt that it will present the data procured in a thoroughly scientific aspect. It may eventually be found both helpful and instructive if the results obtained in London, Glasgow, and Belfast are put together for comparative purposes.

HARD WATER-SUPPLIES.

It is a popular but probably wrong impression that hard drinking waters are prejudicial to the health and, moreover, are injurious to delicate skins when used regularly for ablutionary purposes. Gout, kidney disease, and dyspepsia by an interesting line of reasoning have been supposed to be due to, or aggravated by, the drinking of excessively hard water. Some mysterious connexion between the chalk of the water and the formation of "stone" in the kidney or of "chalk" in the joints in gout is a favourite speculation with many, but in the history of the world's water-supplies there is no trustworthy evidence that the drinking of hard water influences for worse these diseases. The idea is, in fact, chimerical, especially when we bear in mind that many waters of repute in gout and kidney disease contain as their principal constituents lime salts. The chalk of "chalky gout" is, of course, due to urates and not to lime. Some years ago a commission of experts in France came to the conclusion on considerable evidence brought before them that a moderately hard water was the best and that persons residing in districts supplied with such water had a better physique than those living in districts in which soft water was used. Similar conclusions were expressed by a committee appointed in Vienna to investigate the same question. In our own country the Royal Commission on Rivers Pollution in 1876 concluded on this subject after a long inquiry that where the chief sanitary conditions prevail with tolerable uniformity the rate of mortality is practically uninfluenced by the softness or hardness of the water supplied to different towns, and the average rate of mortality in the different water divisions varies far less than the actual mortality in the different towns of the same division. It has further been stated that the very soft water supplied to Glasgow from Loch Katrine has led to an increased prevalence of rickets but there is not a particle of evidence in the health returns of the city that such is the case. A change of drinking water does, however, affect occasionally some persons in the form of a disturbance of the gastric organs. Thus symptoms of common dyspepsia have been remarked in persons who have had occasion to adopt temporarily a soft drinking water-supply after being accustomed to drinking hard water and *vice versa*. Pure distilled water is known to cause gastric catarrh by reason of its power of penetrating the tissue cells, which then swell. Obviously such a process in the stomach may lead to gastric catarrh. On the whole, therefore, there does not appear to have been any serious count sustained against the use of hard waters on the score of their affecting unfavourably the health of the drinker. The innumerable inconveniences experienced by every householder who is provided with an excessively hard water-supply form another question, and withal a serious one. The constant blocking of the hot-water pipes with lime salts entailing the frequent cleaning of the boiler and the pipes, the

latter sometimes having to be removed altogether, is a real hardship to householders served by a very hard water-supply. There can be little doubt that such being the case the risk of an explosion occurring in the kitchen boiler is immensely increased. We have seen pipes which were taken out of a house in the district supplied by the Kent Company and which had only been in use a few months so thickly lined with chalk as hardly to permit of the passage of a pen-holder through them. The waste caused by hard water is enormous, the life of utensils and pipes is considerably shortened, and the loss of heat is very great. The deposition of lime salts practically destroys the conducting power of the metal of cooking vessels, kitchen boilers, and pipes. For cooking purposes, also, hard water is objectionable; it hardens the tissues of vegetables and meat and thus tends to make them indigestible. These facts furnish ample reason for giving serious consideration to the proposal to soften, or partly to soften, certain of the very hard water-supplies in England. If it can be done in some places, of which the Colne Valley is an example, with economy and with great advantages to the consumers it can be done in all.

HATPINS IN PUBLIC VEHICLES.

A FREQUENT correspondent writes: "Most men, even those least acquainted with the details of feminine attire, are aware that women who wear hats retain them in position by transfixing them with two or more 'hatpins,' or fine steel skewers, about eight inches in length, having more or less ornamental knobs or buttons at one end and tapering to sharp points at the other. These pins now and again figure in the accounts of proceedings at the police courts as weapons used by women of violent temper either in attacking an enemy or in defending themselves against arrest by the police. I consider that they are besides a source of danger to the general public through the negligence rather than the malevolence of their wearers. In the headdress of a well-dressed woman they are useful for the purpose for which they are intended and are not conspicuous except as ornaments, the button or knob alone being exposed to view, the point either concealed or only slightly projecting. Slatternly and untidy women, however, not exclusively of the poorer classes, wear them in such a manner that two or three inches, or even more, of their sharp ends project beyond the hat or protrude themselves through the coils of hair which the hats surmount. When the wearers are nursemaids mistresses will do well to see that their children's eyes and features are not exposed to danger through the slovenliness of their servants, but, of course, when the mistresses are slovenly also no such supervision is to be expected. The adult public, including the sex to which hatpins are not a necessity, are principally concerned with those worn by persons with whom they are, literally, thrown in contact when travelling in omnibuses, tramway cars, and trains. In all these means of conveyance the tendency is towards increased speed and rapid stopping and starting, so that we frequently see those entering or leaving a carriage stagger against one another, or against those seated, and scarcely less often a sudden jerk causes a row of seated passengers to sway more or less violently according to their individual weight and stability. It may be suggested that if all sway in unison, actuated by the same impulse, their heads will remain at unchanged distances from one another; but, in fact, all are not affected alike, and a man who remains tolerably rigid may have the head of a less stalwart neighbour brought into very close proximity with his own. I speak from personal experience and hence this letter. He may receive nothing more serious than a blow from a well-padded skull, but if there is a spear as sharp as a needle to accentuate such a blow, a

needle, moreover, which has certainly not been sterilised in the ill-kept hair through which it has passed, he may quite conceivably be hurt." We have drawn attention to the dangerous contingency before in our columns and the risk has not decreased with the advent of motor omnibuses, the passengers of which are more liable to be rolled against one another than are those in any other class of public vehicle. As a matter of fact, no serious accident has, so far as we know, yet happened, but as motor omnibuses are increasing we may some day hear of a traveller summoning up courage to remonstrate with a dangerous neighbour. On such an occasion he might fittingly point out to her that her hatpin is but a means to an end and is no more intended for exhibition, so far as its mechanical details are concerned, than the other apparatus by which she and her masculine fellow travellers retain their garments generally *in situ*. More often, however, bashfulness will prevail and the threatened person, after an apprehensive glance or two at the danger, will either resign himself to his fate, hoping for the best, or will take an early opportunity of changing his seat. Some day—it will not be till after an accident has occurred—we may see a negligent lady figuring as a defendant in a court of law, and in this connexion we may remind married men of their own liability to pay damages incurred by their wives. Pins are obtainable, we believe, having counter-knobs to screw on to their points, but they are unpopular because they are difficult to use and also more expensive, although, on the other hand, they afford a double opportunity for the display of ornament. In the absence of any more ingenious device than these the careful adjustment of pins of a suitable length would appear to be the only remedy possible.

INTRACTABLE HICCOUGH DUE TO LATENT TUBERCULOSIS OF THE PONS AND MEDULLA.

At a meeting of the Société Médicale des Hôpitaux of Paris on Jan. 18th M. Henri Lamy and M. Maurice Cleret reported the following interesting case. A man, aged 43 years, was admitted into hospital on Oct. 28th, 1906. He had enjoyed good health until four years previously when he had left pleurisy. Subsequently he suffered from cough and grew thin. On admission he was emaciated and coughed and expectorated considerably. The sputum was purulent. Examination of the chest showed dulness at the left apex in front and behind and at the right base. The respiration was cavernous at the left apex and there were numerous moist râles at the right apex. At the right base there were pleural friction and diminished vesicular murmur. The case ran the ordinary one of fatal pulmonary tuberculosis, but about a fortnight before death, which occurred on Dec. 28th, the patient complained of persistent hiccough. This continued until the last two days of life, when delirium and vomiting appeared. Coma followed and Kernig's sign was obtained. Thus there were typical symptoms of meningitis on these days. The necropsy showed extensive pulmonary tuberculosis and no other visceral lesions. There was recent miliary tuberculosis of the cerebral membranes. A large tubercle of the size of a small pea was found on the posterior surface of the inferior part of the left inferior cerebellar peduncle. It had hollowed out a cavity by pressing aside the fibres of the peduncle. Its internal and superior extremity was in contact with the floor of the fourth ventricle. Sections of the brain showed no other lesions except a tubercle of the size of a hazel-nut at the lower part of the pons. It is noteworthy that these tumours remained quite latent until a fortnight before death when the intractable hiccough occurred. At the following meeting of the society M. O. Gandy and M. Lévy-Valensi reported a similar case in a man of the same age, who

was admitted into hospital on Dec. 13th, 1906. He had had sero-fibrinous pleurisy five months previously. After this he suffered from cough and loss of flesh. Eight or ten days before admission continuous headache began. In the streets the patient forgot his way. Three days before admission hiccough began. Five, six, or eight times a minute violent contractions of the diaphragm occurred accompanied by characteristic closure of the glottis and quivering of the whole abdominal wall and lower part of the thorax. The patient was apathetic and with difficulty could be made to answer "yes" or "no" to questions. He muttered more or less incomprehensible words. At night he was delirious. There was slight tremor of the upper limbs. The temperature was a little raised and the pulse was rapid and regular. There was no stiffness of the neck and the pupils were regular. On the following day Kernig's sign was obtained. The patient became torpid and died comatose on Dec. 19th. Intractable vomiting persisted by day and by night until the end. Hiccough is evidently a rare variety of the disturbances of the respiratory rhythm which may occur in meningitis, such as pauses, polypnoea, and Cheyne-Stokes respiration.

* A day on which at least 0.04 in. has fallen.

The above figures represent the temperature and rainfall for last month at certain selected places in this country and abroad. If they are compared with the corresponding figures for January which were published in THE LANCET¹ it will be seen that at all the foreign stations except Berlin, Paris, Palermo, and Algiers there was a rise of temperature, while in this country a fall was experienced. As is invariably the case in winter, the nights at the Scilly Isles were much milder than in any other part of this country and, as can be seen by the mean minimum temperatures, they were also considerably milder than those at Nice, Florence, and Blarritz, and only a little cooler than those at Naples and Palermo. Visitors to Malta and Algiers, however, enjoyed a night temperature as mild as, or milder than, that of the afternoons at nearly every in this country,

¹ THE LANCET, Feb. 16th, 1

and visitors to Lisbon experienced the same temperature at night as that prevailing during the day-time at Bath, Nottingham, and Jersey. The days at Nice and Florence were several degrees warmer than they were at Bournemouth, Sandown, and Torquay but after sunset the English resorts retained their warmth to a much greater extent, so that the nights were no cooler than those of their southern rivals. The average diurnal range of temperature was in nearly every instance less at our own southern and south-western resorts than abroad, but the range of only ten degrees at Naples and Malta was no larger than that at Sandown and Torquay and a degree less than it was at Bournemouth. At all the foreign resorts except Naples, Malta, Algiers, and Lisbon the sheltered thermometer touched, or fell below, the freezing-point, and the only place in the whole of the United Kingdom that escaped the frost was Scilly. At Nice and Blarritz there were nine frosty nights and at Florence 12. Except at Algiers the month was nowhere very rainy; the driest spots abroad were the Riviera, Northern Italy, and the coast of Portugal, while in this country London was amongst the driest. The sunshine is not recorded at the foreign stations, but in this country, especially along the south and south-west coasts, the month was particularly bright, most places registering an average of about three and a half hours per day. It is, however, probable that most of the Mediterranean resorts enjoyed a longer duration considering that the sun in that latitude was above the horizon for a much longer period.

MEDICINE AND THE UNIVERSITY OF OXFORD.

As will be seen by particulars given in another column, "the Master and Fellows of the College of the Great Hall of the University, commonly called University College in the University of Oxford," have decided to endow a prize for research in any medical science. It is to be called the Radcliffe Prize in memory of that Dr. John Radcliffe who was so bright an ornament of the society in question and who gave so generously towards the funds thereof. This endowment from University College is one more instance of the desire lately shown by various colleges to do something to facilitate the study of medicine so far as their respective finances will allow. The University itself is poor but many of the colleges which may be called constituents of the University are rich, and such as can afford to do so help in many ways those members of the University who are not members of their own society. Research is perhaps more needed in the science of medicine than in any other, for in no other science are there more problems awaiting solution or problems the solution of which would more powerfully affect human happiness, and it is fitting that University College, which was traditionally founded by King Alfred, should try to increase the sum of human knowledge, for, as Alfred himself said, "Though we think upon many things, we have but little perfect understanding free from doubt."

SILVERED SILK SUTURES.

In the *Centralblatt für Chirurgie*, 1906, No. 35, Herr Witzel and Herr Wederhake describe the properties and the mode of preparation of silk sutures impregnated with silver. Silver wire is smooth, unabsorbable, non-absorbent, and easily sterilised, but its stiffness is disadvantageous. Silk impregnated with silver and afterwards treated with an antiseptic and made waterproof with caoutchouc is cheaply and easily prepared; it is one-third stronger than ordinary silk, it is flexible, antiseptic, easily sterilised, and non-absorbent. It is said, in a word, to combine the advantages of silk and silver wire without possessing their disadvantages. The silk is silvered in the following way. The silk is wound

on glass plates and soaked successively for 12 hours in ether, to remove fat, for 12 hours in absolute alcohol, and then for 20 minutes in a 10 per cent. solution of hydrogen peroxide. The silk is then transferred to the silver solution, which is prepared by precipitating a 1 per cent. solution of silver nitrate by the addition of sodium hydroxide and dissolving the washed precipitate with a minimum of ammonia solution. Next the suture is dried in an oven at 100° C., soaked in chloroform for two hours, and then in a 16 per cent. solution of caoutchouc for 12 hours. It is washed quickly in chloroform and dried, and finally the silvered silk is boiled for ten minutes in a 1 per cent. solution of mercuric chloride, and kept permanently in this solution. The suture requires to remain about one hour in the silver solution in order to become perfectly black, showing no white spots in transverse section.

THE LATE DR. ORONHYATEKHA.*

LIKE Hiawatha, the legendary saviour of his people, Dr. Oronhyatekha, whose death was recently reported at Georgia, prayed—

"Not for greater skill in hunting,
Not for greater craft in fishing,
Not for triumph in the battle,
Nor renown among the warriors,
But for profit of the people."

and in his nature formed a remarkable contrast to the general proclivities of the picturesque race to which he belonged. He was of the Mohawk tribe of the Six Nations and was born in 1841 on the tribal reserve near Brantford, Ontario. After receiving some elementary education under great difficulties he became a schoolmaster in his native reserve and subsequently entered Toronto University, where his intelligence and complete grasp of civilised life attracted the attention of his teachers. When the King, then Prince of Wales, visited Canada in 1860 Oronhyatekha was chosen by the chiefs of the Six Nations to present an address to his Royal Highness who, charmed with the intelligence and manner of the young Indian, offered to pay the expense of his further education at Oxford. The offer being accepted, the first, and probably the only, Red Indian Oxonian was placed under the care of Dr. Henry Acland, Regius Professor of Medicine, and on his return to Canada he entered the medical profession there and was well known as an excellent organiser. He was the first secretary of the Hastings County Medical Association and for the last 26 years of his life was Chief Supreme Ranger of the Independent Order of Foresters, a society in which he took a keen and active interest. Dr. Oronhyatekha married in 1863 a woman of his own blood, a great-grand-daughter of the chief Thayendaneagea who in his day was famous for his enlightened outlook upon life, his humanitarian qualities, and his loyalty of purpose. Dr. Oronhyatekha was a Freemason, an Orangeman, and a Good Templar. The son of the deceased Indian chief, William Acland Heywood Oronhyatekha, is an M.D. of Toronto University.

AN IMPROVED METHOD OF DETERMINING MORPHINE.

AN ingenious method of determining small or large quantities of morphine has been suggested by Mr. Thomas Tickle, F.I.O., in the *Pharmaceutical Journal* of Feb. 16th. It presents many points of originality and promises to be of value in toxicological examinations for morphine. The essential point in the process consists in the employment of metacresol in addition to amyl alcohol as a solvent of the alkaloid. Metacresol is a far better solvent of morphine than is amyl alcohol, but it is partly soluble in water, a difficulty which is surmounted by employing a mixture of these solvents in the proportion of 2 to 1. The outline of the process, full particulars of which

will be found in the original paper, is as follows: The alkaloid is liberated with sodium bicarbonate and agitated with a mixture of metacresol and amyl alcohol, and after observing certain precautions the alkaloid is extracted from the mixed solvents by agitation with acetic acid. The solution of morphine acetate obtained in this manner is placed in contact with the vapour of ammonia, whereby the alkaloid is deposited in a crystalline form. The crystals of morphine are then dried and weighed. This process is serviceable for dilute solutions of morphine and is especially useful in toxicological examinations, as the metacresol fixes and eliminates the albuminoid extractive material which often occasions considerable difficulty when working with the methods hitherto employed. The paper contains full experimental proof of the excellence of the method, showing its undoubted superiority over methods based on the use of amyl alcohol alone as a solvent which have hitherto given the best results.

THE MILK QUESTION IN NEW YORK.

THE *New York Medical Record* of Feb. 23rd states that the board of aldermen of that city has taken up the milk question and an ordinance has been proposed providing that all milk sold at retail shall be either sterilised or pasteurised, unless the milk has been bottled in dairies under the supervision of inspectors of the health department and each bottle bears the health department's seal placed on it by one of the department's inspectors. The milk question is arousing the attention of health authorities in many parts of the United States. In Illinois the State pure food authorities have found that only from 30 to 35 per cent. of the milk sold in the various towns of Illinois which they visited was in a satisfactory condition owing to defective sanitary arrangements in collecting and handling it. The lay papers of New York have been urging for some time that all milk furnished to the city should be pasteurised. The medical journals for the most part uphold the New York Health Commissioner in his contention that municipal pasteurisation is not nearly so effective a system for insuring an unpolluted milk-supply as is inspection of the sources of supply. The *New York Medical Record*, in a previous reference to the question in its issue of Feb. 16th, a leading article, points out that inspection alone would be insufficient owing to the fact that the New York milk-supply is drawn from some 30,000 farms scattered through several States, and that to inspect the milk at these farms properly a larger force of inspectors would be needed than the city would care to pay for. Inspection to be of real value must be fairly frequent and thorough. Therefore it is claimed that both inspection and pasteurisation should be employed. It is a healthy sign, at any rate, that in Great Britain and in the United States interest is being gradually excited in the quality of the milk-supply.

NATURAL INCREASE IN THE ENGLISH POPULATION.

THE persistent decline during the last 30 years, both in the birth-rate and death-rate in England and Wales, and the consequent result on the natural increase of the population, are dealt with in an interesting table in the recently issued annual report of the Registrar-General relating to the year 1905. The annual birth-rate, which was equal to 35.4 per 1000 in the five years 1878-80, showed a marked decline in each of the five succeeding quinquennial periods and had fallen to 23.1 in 1901-05. The effect on the population of this decline in the birth-rate was to a considerable extent counterbalanced by the persistent decline in the annual death-rate which steadily fell during the six five-year periods under notice, from 20.8 per 1000 in 1878-80, to 16.0 in 1901-05.

The average annual rate of natural increase of population, by excess of births over deaths, which was equal to 14.6 per 1000 in 1876-80, showed, however, a steady decline in the four following five-year periods to 11.6 in 1896-1900; but it recovered to 12.1 per 1000 in 1901-05, during which period the decline in the death-rate was proportionately greater than the decline in the birth-rate. The actual increase of the English population is, of course, influenced by the balance between immigration and emigration as well as by the balance between births and deaths; but the effect of this factor was so slight during the ten years 1891-1901 that the difference between the number of the population enumerated in 1901 and the estimate based solely on the excess of births over deaths in the ten years was only equal to 2.3 per 1000. Failing complete record of immigration and emigration, the estimate of the English population in the middle of 1905, adopted by the Registrar-General in his last annual report, is based on the assumption that the rate of increase that prevailed in the last intercensal period has since been maintained. The result of this estimate assumes that the loss to the English population between the date of the last census and the middle of 1905 by excess of emigration over immigration was 105,442, or nearly 25,000 per annum.

HAIR-BRUSHING BY MACHINERY.

THE machine brush, especially if it be driven by electrical means, is one of the proud acquisitions of the modern barber. It is commonly looked upon as a sign that the business of the hairdresser is conducted upon principles abreast of the times. A machine brush electrically propelled, together with some attempt at an aseptic or antiseptic practice in connexion with hair-cutting, shaving, and shampooing, serves to bring the proprietor of such an establishment into some sort of scientific reputation from the point of view of his patrons. Cleanliness is almost as great a *sine qua non* in the conduct of the affairs of a barber's shop as in that of the operating theatre, and therefore the man most deserves success who most endeavours to secure as far as possible the scientific cleanliness of his person and of the instruments used in his business. There is not wanting evidence that the barber's shop has been the means of spreading disease and it is not difficult to suggest the conditions under which such a distribution of pathogenic materials may take place. The sterilisation of razors, combs, brushes, and the hands of the operator may, however, avail much but it is conceivable that the good which this may do may be undone by the revolving brush scattering dust, scurf and so forth from the dry scalp. Thus all the care taken to insure antiseptic conditions may be negated by the whirlwind of particulate matters raised by the machine brush. It should be remembered that the function of the machine brush is not to dress or to arrange the hair but merely to drive out dust and hair-cuttings. The hand brush, of course, plays quite another part; it is used to adjust the hair and very frequently during this process the hair is wetted or oil is applied to it. It is a pity that the machine brush presents this objectionable feature, for apart from its usefulness as a remover of dust and hair clippings it undoubtedly exercises a healthy stimulus to the scalp and may even promote, when reasonably used, the nutrition of the hair. For these reasons the apparatus finds a wide circle of patrons. To preach its abolition may be justifiable on strictly hygienic grounds, but that would mean the banishment of a really useful, if not indispensable, instrument connected with the dressing and treatment of the hair. Its application would be rendered futile by moistening the hair and so the suggestion remains that the objection might be met, perhaps, by conducting the machine-brushing operation in such a manner that dust,

hairs, and scurf would be directed, for the most part, up an exhaust ventilating shaft situated immediately opposite the head of the person who is under operation. Such a measure, too, would secure a supply of fresh air in general in the room.

EPIDEMIC CEREBRO-SPINAL FEVER.

DURING the last six or seven days epidemic cerebro-spinal fever has made its appearance in several fresh localities. In London on March 7th an inquest was held on a girl, aged five months, who had died at Kensal Rise. The medical evidence was to the effect that death was due to cerebro-spinal meningitis and the jury returned a verdict accordingly. The medical officer of health of Poplar reported on March 7th that a fatal case had occurred on the Isle of Dogs. Cases are also said to have occurred at Wealdstone, near Harrow, Middlesex, at Langley Green, near Oldbury, Worcestershire, at the village of Elson in Shropshire, and at Warrington. An alleged case in St. Helens, near Liverpool, was at the necropsy found to be tuberculous meningitis. Two fatal cases are reported from Liverpool. In Glasgow the daily announcement of the cases notified and the deaths has been discontinued since March 4th and in future only a weekly official report will be issued on Fridays. The report for March 8th stated that only 101 cases were under observation. There had then been notified in Glasgow a total of 340 cases with 174 deaths. Since the beginning of March there have been eight or nine deaths from the disease in Leith. In Greenock three patients have recovered and three remain in the hospital. In Paisley there have been 13 cases with nine deaths, and in Govan a total of 26 cases with 14 deaths. In Dundee there have been several cases, some of which are described on p. 739 of our present issue, and there has been a case in Dunfermline. In Belfast nine fresh cases and one death were announced on March 12th. There had then been in that city a total of 177 cases and 96 deaths. In Dublin there has been a total of nine deaths but no fresh case has been notified since March 5th.

THE THERAPEUTIC VALUE OF CACTUS GRANDIFLORUS.

THE therapeutic value of *Cactus grandiflorus*, the night-blooming cereus, in functional disorders of the heart has been considered by some physicians to be such as to warrant the inclusion of the drug in the current edition of the United States Pharmacopœia. The subcommittee on pharmacognosy investigated the question and its results have been published by Professor L. E. Sayre in a recent number of the *Therapeutic Gazette* (1906, No. 12, pp. 812-16). It was found difficult to obtain a supply of trustworthy material, as the greenhouse varieties were not considered to be of value and the plants growing wild in tropical countries occur in many species and varieties. Alcoholic tinctures were made from the fresh stems of authentic material and examined physiologically, with the result that the action of the drug on the heart was found to be slight and uncertain, if not practically nil, as shown by tracings taken from the right ventricle and carotid artery of dogs anaesthetised by chloroform and morphine. The subcommittee came to the conclusion that the drug should not be made official, as it is difficult to obtain and to identify; moreover, it rapidly deteriorates, owing to the presence of an enormous quantity of water, 95 per cent., in the fresh stem, together with mucilage and other easily decomposed bodies. No alkaloid or other definite principle has yet been discovered in the drug; indeed, if one be present there is reason to suppose that its percentage yield would be remarkably low, amounting to no more than 0.00078 in the tincture. For the present, therefore,

the therapeutic value of *Cactus grandiflorus* is open to considerable doubt, in spite of many favourable opinions expressed by clinicians.

THE Department of Public Health of Queensland in a bulletin dated Jan. 28th states that 6 more cases of plague had occurred and been notified. Of these (the numbering follows the cases reported in the bulletin of Jan. 19th) Case 10, a boy, aged 14 years, was removed to hospital on Jan. 20th and died on the 25th. Case 11, a woman, aged 75 years, was the grandmother of Case 10 and had been nursing him. She was attacked on Jan. 19th and died on the 21st, being too ill to be moved to hospital. Case 12, a boy, aged eight years, was attacked on Jan. 19th, and the case was only reported after death. Cases 13 and 14 respectively, a boy aged eight years and a girl aged nine years, came, as did all the other cases, from the New Farm infected area and had been in constant association with the other cases reported. The boy was attacked on Jan. 19th and the girl on Jan. 23rd. Case 15, a male, aged 40 years, was the father of Cases 6 and 7. He was attacked on Jan. 22nd. A plan is attached to the bulletin showed that the outbreak is a typical example of local infection. All the cases are associated with the general and produce stores known as Garnett's, in James-street, New Farm. Dead rats were found in and near these stores previously to the outbreak and all the boys had been playing recently in the stores. With regard to Cases 8 and 9 (the suspect cases) they are convalescent. Bacteriological investigation was negative in both. With regard to Port Douglas, 31 cases have been reported and 1 has proved fatal. They all come from a sugar mill eight miles outside the town.

AN ordinary meeting of the Royal Meteorological Society will be held at the Institution of Civil Engineers, Great George-street, Westminster, S.W., on Wednesday, March 20th, at 7.30 P.M., when a lecture will be delivered on the Exploration of the Air, by Major B. F. S. Baden-Powell. The lecture will be illustrated by models and lantern-slides. The annual dinner will be held at the Trocadero Restaurant, Piccadilly-circus, W., on Tuesday, June 18th, at 7 P.M.

A MEETING will be held at the Mansion House on Wednesday, March 20th, at 3 P.M., with the permission of the Lord Mayor, to promote the interests of the Second International Congress on School Hygiene to be held in London in August next. The following are announced as speakers: Sir Lauder Brunton, Sir John Cockburn, Dr. T. J. Macnamara, M.P., Sir Richard Martin, and Sir Edward Brabrook.

Dr. L. E. Hill and Dr. H. A. Caley have been nominated as candidates for the two vacancies upon the Senate of the University of London. The election will resolve itself into a contest between those who do and those who do not believe in the necessity for the erection and foundation of an Institute of Medical Sciences in connexion with the University of London.

THE death is announced, on March 10th, at Bournemouth, of Dr. A. E. Sansom, consulting physician to the London Hospital. Dr. Sansom had written much upon diseases of the heart. We hope to give details of his career in a future issue.

A PAPER by Mr. Noel A. Humphreys, I.S.O., entitled "The Alleged Increase of Insanity," will be read before the Royal Statistical Society at 9, Adelphi Terrace, Strand, London, W.C., on Tuesday, March 19th, at 5 P.M.

THE RÔLE OF THE BLOOD PLASMA IN DISEASE.

BY HARRY CAMPBELL, M.D., B.S. LOND., F.R.C.P. LOND.,
PHYSICIAN TO THE NORTH-WEST LONDON HOSPITAL AND TO THE
HOSPITAL FOR DISEASES OF THE NERVOUS SYSTEM,
WELBECK-STREET.

IV.¹

INFLUENCE OF THE PLASMIC ENVIRONMENT ON THE DEVELOPMENT OF THE ORGANISM.

THE fact that the evolution of the individual cell is so greatly under the control of its environment prepares us for the conclusion that the development of the organism as a whole is in great measure determined by the environmental influences operating on its constituent cells and by no means solely by a developmental impulse inherent in these cells. How far this is true of embryonic development cannot here be discussed, but that it is true of post-partum life there can be no shadow of doubt. It is safe to predict that were the individual cell environments to remain, during the entire post-partum life, the same as on the last day of intra-uterine life—were the plasmic environment to remain the same, the nervous system never to be stimulated by external agencies, nor the muscle and gland cells energised through their nerves—supposing life were possible under such conditions, it is, I say, safe to predict that little or no development would take place. Growth there would doubtless be, but it would be growth without development—a mere magnification of the infantile type; some glimmering of mind there might evolve, but the mental personality would be built up of visceral sensations alone, rising to no higher level than that of the proverbial oyster.

The structural changes which characterise the various stages in the vital cycle—infancy, childhood, puberty, adolescence, maturity, and old age—are all in large measure determined by the plasma, as also are the changes which take place in the pregnant woman. The composition of the plasma varies with each of these vital stages. As each is reached a particular spring is as it were touched, and the plasma changed in such wise as to induce the structural changes characteristic of the stage attained; during the developmental period the tissues are urged by specific plasmic stimuli to develop along definite lines, in the absence of which stimuli they tend to remain *in statu quo*; while in the final stage they suffer senile decay not so much because they wear out as because decay is deliberately thrust upon them by specific plasmic influences, which thus check that tendency to corporeal immortality which is innate in all living things, and set a definite term to the length of life: the organism commits, in fact, slow suicide through the plasma.² That the various stages of post-partum development are brought about by specific plasmic stimuli is proved by the fact that development may cease at any one of them, if the needed hormonal stimulus be wanting, and by the further fact that in some cases, at all events, it may be made to proceed normally by supplying the plasma with the ingredient which it lacks. Thus in certain cases of infantilism the administration of pancreatic extract is known to have this remarkable influence, and there can be little doubt that the pancreatic hormone which produces this effect is only one among many similar hormones operating during early life. Absence of the thyroid implies, as we know, impeded development, which can to some extent be advanced by the administration of thyroid extract, and the fact that the thymus gland atrophies soon after birth strongly suggests that it also plays a necessary part in development, especially during its earlier phases. Its persistence in cases of Graves's disease is of interest in this connexion.

The influence of the plasma on development is also shown by the phenomena of puberty. It is now known that the secondary sexual characters, both mental and physical, are induced by the presence in the blood of specific hormones derived from the ovaries and testes. Possibly these or kindred hormones begin to be formed in small quantities quite early in life and are responsible for such secondary sexual characters as are observed before puberty, for the boy

¹ Articles I., II., and III. were published in THE LANCET of Feb. 2nd (p. 313), 9th (p. 375), and 23rd (p. 535), 1907, respectively.

² I have elsewhere given my reasons for concluding that senility is essentially a process of slow suicide, committed through the medium of the plasma. See THE LANCET of August 5th, 1905, p. 403.

and the girl show mental and physical differences from quite an early age. When, however, puberty is reached the ovaries and testes are stirred—how we know not, but possibly through the instrumentality of the adrenal glands, the cortical portions of which have been found to be hypertrophied in cases of premature puberty—into increased activity, and begin to pour their hormones plentifully into the blood. As a result of this the entire organism is stirred to its depths; the metabolism of its every cell is altered, development is pushed forward along specific lines, the bodily conformation changes, new feelings arise, and the individual looks out upon the world with altogether other eyes. And all this at the prompting of a subtle essence yielded by two small glands. Surely no magic spell of fable ever wrought change more wonderful.

This mechanism generally becomes effective at about the fourteenth year, but sometimes it comes into premature operation, as early, it may be, as the second year, as in a patient of my own; sometimes, on the other hand, its action may be delayed for a few years, or even remain in permanent abeyance.

Among the hormones which determine growth and development must be reckoned those which are formed in connection with menstruation and pregnancy. Menstruation, as Marshall and Jolly have shown, is excited by an ovarian hormone; and these observers have also demonstrated that the uterine changes which bring about the fixation of the impregnated ovum are likewise induced by an ovarian hormone, apparently derived from the corpus luteum, which, as is well known, undergoes considerable enlargement during the first three months of pregnancy. The remarkable transformation which the pregnant woman undergoes is due, wholly or in part, to the absorption of foetal hormones. Among the changes thus brought about is the active mammary development, as the striking experiments of Starling and Lane-Clayton have so admirably demonstrated. The metabolic changes induced by the alteration which the plasma of the menstruating and pregnant woman undergoes, interesting and important though they be, are too numerous to be entered into here. I will merely refer to the influence of pregnancy in removing anæmia and improving nutrition. I have seen a slender anæmic girl increase so rapidly in weight during the first three months of pregnancy that her friends have failed to recognise her in the street.

In order that we may fully appreciate the influence of the plasma on development it is necessary to take due account of the fact, already insisted on, that every new form of functional activity is attended by structural change, and when we consider the many successive changes which the plasma undergoes during the years of development, and the numerous new forms of activity which are in this way called forth, we are better able to realise how it is that the plasma comes to influence development so profoundly. Nor does the influence of the plasma in determining the normal vital cycle end with the attainment of maturity: it continues throughout life; and just as the changes which this fluid undergoes before maturity determine in large measure the developmental changes which lead up to that epoch, so do the plasmic changes which take place during maturity and senescence largely determine the structural changes which then occur. Even during the stage of maturity the individual does not remain stationary; each day he grows structurally older; each day he makes some advance towards senility. With the exception of the highest nerve centres which may continue to evolve some time after the tissues in general have matured, these changes are for the most part in the direction of degeneration, and such degenerative changes are due, not so much to a wearing out of the cells of the body, or to an innate tendency to degeneration at a certain period of their career, as to specific agencies operating on them through the plasma. These agencies probably begin their work of destruction soon after maturity is reached, remaining, however, in partial abeyance until the age of 60, or thereabouts, when they may come into more active operation; and just as puberty may begin prematurely or postmaturely, according to the time at which the plasma becomes pubescent, so may senile degeneration occur earlier or later, according to the time at which it grows senescent. On the one hand senility may begin in childhood, with the characteristic phenomena of blanching of the hair, wrinkling of the skin, and hardening of the arteries; and, on the other hand, it may be delayed, even as late as the ninth decade, as in the case of one of my patients who in many respects is as young as the average man of 50.

In those who live to a great age senility generally comes on late and advances slowly. When it begins early it is apt to appear suddenly and to advance rapidly.

We do not yet know what constitute the special characteristics of senile plasma. It is probable that most of the plasmic constituents undergo some alteration with advancing years, but there are good grounds for concluding that the most characteristic changes, and those having the greatest influence in producing senile degeneration, pertain to the hormones. What causes these hormonal changes has yet to be discovered; it seems not improbable that they result in large measure from atrophy of certain hormone-yielding tissues, such as the thyroid. Such an assumption must not be taken to imply, as some might argue, that senility is, after all, due in the last resort to a primary atrophy, or decay, of some part of the organism; it is not necessary that the assumed atrophy should be a primary one; it might occur secondarily to some specific environmental influence. The atrophy of the thymus gland at an early period of life is assuredly not due to senile decay of its component cells; it is comparable to the atrophy and disappearance of other foetal structures and is evidently due to some such process as vascular shrinkage, or the presence in the blood of a substance destructive to the cells of the gland—at any rate, to an environmental influence of some kind; and it would be possible for the atrophy of the thyroid gland, which we have assumed to be one of the causes of senile degeneration, to be induced in a similar way. In short, the process which starts senile degeneration need not of itself be of a primary, spontaneous, degenerative kind. It is, indeed, possible for heightened functional activity in one tissue to set up degenerative changes in others; thus it has been shown that atheroma may be induced in rabbits by injecting them with adrenalin, and it is conceivable that that heightened activity of the adrenal glands may be one of the causes of atheroma—that such heightened activity may constitute, in fact, one of the mechanisms by which senility is induced. Be this as it may, the phenomenon of experimental atheroma clearly shows that senile degeneration may be initiated in other ways than by a wearing out, or spontaneous decay.

I have said that the changes which in due course take place in the hormonal constituents of the plasma may be partly responsible for senile decay, but it must not be thought that the plasmic changes which senile blood undergoes and which induce the degenerations characteristic of senility are simple in nature. Like the kindred changes which occur during, and which are largely responsible for, development, they are of a highly complex kind. We must remember that any alteration in plasmic composition leads to modified metabolism, that this modified metabolism itself reacts on the composition of the plasma, that this plasmic alteration again causes a further modification of metabolism, and so on indefinitely. In this way the plasma is prevented from remaining stationary in composition, and is made to undergo a series of changes which are continually bringing new forms of activity into operation, with their attendant structural changes; those structural changes which accompany the new activities excited by the successive plasmic changes occurring during developmental life being evolutionary, and those which attend the activities excited by the successive changes which senile blood undergoes dissolutionary.

THE PART PLAYED BY THE PLASMA IN DETERMINING THE ANATOMICAL CHARACTERISTICS OF RACE.

I have already pointed out that the composition of the plasma is peculiar for each race, and since plasma influences structure we are now confronted with the question whether the anatomical characteristics of race may not in some measure be due to racial differences in plasmic composition. That many undiscoverable differences are thus induced is certain, as also others more obvious—e.g., the tendency to leanness or obesity, but the question arises whether some of the more obtrusive anatomical features of race may not have a similar origin. Many considerations suggest that they may. Consider, for example, the effect of disease in rendering individuals alike. We may place two men suffering from the same disease side by side, and though they may never have seen each other before they might be taken for brothers. This likeness between individuals suffering from the same disease may be observed almost every day in the case of such diseases as granular kidney, myxœdema, paralysis agitans, and acromegaly, in each of which the individual is moulded

—and perhaps even tinted—in a peculiar way by a peculiar condition of plasma. Acromegaly is especially interesting in this connexion on account of the remarkable anatomical changes which take place in it. Possibly the condition of the plasma inducing them is connected with the hormonal function of the pituitary body, but whether or not such is the case, it is certain that the changes in question are induced through the plasma, for there is no other medium through which they can be brought about. I have in another place³ attempted to show that most of the anatomical features of this disease are to be observed in the anthropoid apes, and that the acromegalous man resembles the latter in the following particulars:—“The possession of cranial crests, huge supra-orbital ridges, prominent molars, long nasal bones, massive prognathic jaws, and greatly developed cranial sinuses; in the prominence of the eyes, wrinkling of the lids, furlrowing of the forehead, breadth and fleshiness of the nose, thickness of the lips, shape of the ears; in the shortness and thickness of the neck; in the forward bend of the spine and consequent stoop; in the straightness of the sacrum and coccyx and length of the cervico-dorsal spinal processes; in the shape of the thorax, sternum, and pelvis; in the formation of the hands and feet, especially as regards the existence of pads, separated by deep furrows, on the palms and soles, and in the longitudinal striation of the nails; in the bowing of the legs, the massiveness of the skeleton generally, and the great development of the muscular system, especially of certain muscles—to wit, the trapezius and tensor vaginæ femoris; in the coarseness and looseness of the skin, the excessive growth of hairs, and the tendency to pigmentation; in the scanty adipose deposit in the mammae, and the great size of the clitoris; in the depth of the voice, the abdominal character of the breathing, the great susceptibility to cold, the excessive activity of the cutaneous glands, and the keenness of the sense of smell.”⁴

INFLUENCE OF THE PLASMIC ENVIRONMENT IN CAUSING DISSOLUTION.

We have next to consider the influence of the plasmic environment in causing structural dissolution other than that due to spontaneous senile degeneration of the cell. In so doing I shall again refer to the individual cells rather than to the tissues which they form, but it is obvious that when several of the cells constituting a tissue degenerate we have to do with tissue as well as cell degeneration. It is necessary to observe here that the degenerations cover a much wider field than those discoverable by the microscope. It is only when the dissolution has advanced to a certain depth, as when, for example, the dendrites of a neuron or the transverse striæ of a muscle fibre have disappeared, that its existence can be demonstrated by the microscope, but it must not be forgotten that such *obvious dissolution is always preceded by undiscoverable dissolution, of which there are many stages, at any one of which the degenerative process may stop, and the existence of which has to be sought for in the functional sphere.* All organic diseases are, in fact, preceded by a phase—shorter or longer in duration—which may be described as “functional” in the sense that the cell dissolution underlying it cannot be microscopically demonstrated. This may be observed in the early stages of such diseases as tabes dorsalis and progressive muscular atrophy. Sometimes, indeed, a disease proceeds to a fatal termination without any lesion being discoverable post mortem to account for it, as may happen in myasthenia gravis; just as, contrariwise, marked structural degenerations, for example, in the brain, may often be observed post mortem without having given evidence of their presence during life.

In tracing the vital cycle of an individual cell, as exemplified by the neuron, we saw reason to believe that it rarely degenerates spontaneously—i.e., independently of specific environmental influence, and that even senile degeneration and such disorders as the family palsies, in which the case for spontaneous degeneration is *primâ facie* so strong, may be largely extrinsic in origin. Certain cells of the body normally degenerate and die after a given term

of existence, their place being taken by other similar cells. Such is the case with the chromocytes and some gland cells, and also, according to Pavy, with the lymphocytes which he believes to play an important part in the conveyance of protoid and carbohydrate from the intestines to the tissues.⁵ How far such degeneration occurs spontaneously, and how far as the result of extrinsic causes, is not easy to determine, though what has recently come to light regarding pathological hæmatolysins makes one wonder whether the normal decay of chromocytes may not be due to the action of physiological hæmatolysins—i.e., to the operation of an extrinsic agency. Excluding, however, such possible instances of spontaneous dissolution and those of genuine senile degeneration (in which some degree of inherent causation may be admitted), we may say that *degeneration never occurs spontaneously in a normally evolved cell.* I say in a “normally evolved” cell. One which has not evolved normally—the evolution of which, that is, has either stopped short of the normal goal or proceeded on abnormal lines—is doubtless predisposed to degeneration and may conceivably degenerate spontaneously—i.e., even though it be subjected to normal environmental influences. But it has to be remembered that defective cell evolution is itself often due to environmental fault, and if a cell the normal evolution of which has been thus prevented should subsequently degenerate, even though normally environed, we should not be justified in altogether exonerating the environment from a share in the causation of that degeneration. Whenever, therefore, we meet with cell degeneration we must—with the reservation given—conclude either that its environment is faulty or that it has not undergone normal evolution. Now often our only means of ascertaining during life whether a cell or system of cells has or has not evolved normally is by reference to functional activity; we must, namely, regard functional efficiency as the chief indication of structural efficiency. If, therefore, a system of cells—e.g., neurons in the case of Friedreich's disease or muscle cells in the case of amyotrophies—has for years carried on its functions aright, one may legitimately doubt whether the cells are structurally defective or, at least, whether they are themselves wholly responsible for the premature degeneration which they undergo.

In this connexion I may refer to the observations of Sir William Gowers on what he terms abiotrophy, i.e., a primary cell-atrophy due to an inherent weakness of zygotic origin. Among the instances he adduces are: (a) the baldness which so frequently comes on in men after adult life, a form of atrophy he attributes to a primary “failure of vitality in the follicles”; (b) the idiopathic muscular atrophies, in which he assumes “a defect of vital endurance”; (c) a rare form of atrophy of the spinal motor neurons, which commences about the end of the first year of life; (d) those family palsies which result from degeneration in the pyramidal tracts; (e) those other family palsies in which the posterior and lateral columns degenerate (Friedreich's disease); (f) cases of optic atrophy in which several members of the same family go blind; and (g) cases of progressive muscular atrophy and bulbar paralysis which “often come on without apparent cause simply because the term of life for these structures is reached sooner than for the vital organs.”⁶

Now I admit that these cases are among the most likely instances of genuine spontaneous cell atrophy, but I am not satisfied that even they are wholly spontaneous and to be explained by assuming an inherent lack of cell vitality. The atrophy of the hair follicles which causes ordinary crown baldness in men is surely secondary—the result, i.e., of defect in the local plasmic supply, due to strangulation of the scalp vessels by pressure of the hard-rimmed hat against the resisting skull; and as regards the neural atrophies Sir William Gowers himself admits some degree of plasmic causation in certain of them—e.g., the optic atrophy which may be initiated by tobacco poisoning. The more one reflects upon the potency of the plasma to pick out, and initiate degeneration in, definite groups of cells, the less need does there appear to assume the existence of primary cell degeneration.

The environmental influences capable of causing degeneration may, like those involved in evolution, be classed under two heads—the plasmic and the non-plasmic. Regarding the latter it will suffice to recall the

³ The Scalpel, 1896.
⁴ Do not these resemblances suggest that in acromegaly the blood takes on some characters belonging to that of man's anthropoid ancestors? Be this as it may, we have in it a disease in which not only the soft parts but the very bones are profoundly altered, and there can be no doubt that acromegalic changes may occur within physiological limits. One not infrequently sees perfectly normal individuals with massive features, prominent supra-orbital ridges, heavy mandible, large hands and feet, deep voice, and other acromegalic characters.

⁵ On Carbohydrate Metabolism, 1906.

⁶ Lectures on Diseases of the Nervous System, second series, 1904 p. 96 et seq.

fact, already insisted on, that most of the cells in the body—all the neurons and muscle cells and probably many of the gland cells also—need for their normal vitality, the continual influx of nerve impulses, any interference with which tends to cause them to degenerate. With regard to the plasmic influences the conditions of the plasma capable of setting up degeneration pertain (1) to defective composition; and (2) to defective circulation.

1. *Degeneration from defective composition of the plasma.*—The varieties of morbid plasma which may cause degeneration are innumerable, and when we reflect that each variety affects the tissues in a way peculiar to itself, that every form of disturbed activity thus resulting is, according to the principle already laid down, attended by a structural change, and that such structural change must necessarily be of a degenerative kind, it follows that the degenerations are not, as we are wont to think, limited to the few forms, such as the fatty and the amyloid, which are easily identifiable, but that they must be well-nigh as numerous as the varieties of morbid plasma causing them.

It is not possible in this place to do more than touch very briefly on the subject of plasmically induced degenerations. Regarding those arising from defects in the nutrient ingredients of the plasma we know little. Starvation, leading as it does to impoverishment of the plasma, produces atrophy which may proceed to fatty degeneration; excess of sugar in the blood (or some morbid state of the plasma attendant upon that excess) may cause degeneration, as shown, e.g., by the frequent occurrence of cataract in diabetes; deficiency of hæmoglobin predisposes to fatty degeneration; and other kinds of degeneration, including sclerosis of the spinal cord, are also met with in the graver forms of anæmia, though how far they are due to the anæmia and how far to the associated toxæmia we cannot at present say.

That defects relating to the hormonal constituents of the plasma may cause degeneration is shown by the tissue changes met with in such diseases as myxœdema and acromegaly, and by the occurrence of atheroma in animals as the result of injecting adrenalin. As yet, however, we know but little regarding the nature of the degenerations arising from this cause. But by far the most important among the innumerable defects of the plasma capable of setting up degeneration are those pertaining to its excretory constituents—i.e., substances which, be they normal or abnormal constituents of the blood, demand elimination. Some of these excreta may—at all events when kept within proper limits—be innocuous; when, however, any of them interfere in the slightest degree with the normal vitality of the cell they must be regarded as poisons and as producing some degree of degeneration. This is true of all the poisonous excreta, whether products of normal metabolism occurring in poisonous quantities, poisons formed as the result of morbid metabolism, poisons (e.g., drugs) introduced from without, or, finally, the endless varieties of bacterial poisons. As instances of degeneration from one or other of these classes of poisons we may cite the peripheral neuritis of diabetes, the fatty degeneration of metallic poisoning, and the Zenke's degeneration of typhoid fever. The truth that in the process of cell degeneration dissolution may proceed to any conceivable depth, down to the absolute destruction of the cell, is well illustrated by the action of these various poisons. Sometimes the dissolution they produce is so slight as to be undiscoverable; at other times it results in gross structural change; sometimes it takes many years for the poison to produce such change; in other cases its action may be so virulent as to destroy the cell within a few days. In this latter case we speak of the poison as a cytolytic or cell dissolver, but one may well question whether there is any essential difference between the action of such a poison and one which takes a long time to produce gross change, between the most virulent cytolytic causing rapid solution of the cell and the blandest poison serving but temporarily to disturb its functions.

The production of cytolytics is one of the many marvels of antibody formation; it is found, for example, that if the renal cells of one kind of animal are injected into another kind of animal the plasma of the latter may acquire the property of destroying the renal cells of the former; and similarly in regard to spermatozoa, hepatic, and other cells. Whence the question arises whether kindred substances may not be formed in, or gain entrance to, the animal body, either as the result of morbid metabolism or microbic agency. There

is at present no evidence that the organism is capable of developing cytotoxins as the result of the disintegration and absorption of its own parenchymatous cells.¹ Be this as it may, it is certain that, whenever a certain type of cell is picked out, to the exclusion of other cells, and rapidly destroyed, it must be from the action of some such substance. It does not seem possible, however, to distinguish sharply between such highly virulent poisons and those causing more gradual destruction. It appears to be more convenient to group all the poisons capable of effecting cell destruction under one head, and to arrange them according to the rate at which they accomplish the destruction. Such a procedure enables us to group together a large number of widely divergent affections, some of which may now be considered.

Acute yellow atrophy of the liver is certainly caused by a chemical substance having a destructive action on the liver cells. But this disease is not the only one in which epithelial cells undergo rapid degeneration; the same thing may happen with other glands—e.g., the pancreas—when we must assume the operation of some substance which has a selective action on the pancreatic cells. In other cases—e.g., granular kidney—the epithelial degeneration is more gradual, and, as already observed, the difference between poisons producing such gradual destruction and the more virulent cytolytics is one of degree only.

The symmetrical degenerations of the nervous system are produced by the action of similar poisons. It is indeed probable that, excluding perhaps the primary senile degenerations and certain of Sir William Gowers's abiotrophies, all the so-called primary degenerations of the nervous system are plasmically induced. Sometimes the poison causes rapid destruction of the neurons, as in infantile paralysis, while in other cases—e.g., tabes dorsalis—years may elapse before the affected neurons are completely destroyed.

Among the degenerative changes which result from poisoned plasma are those which occur secondarily to inflammation, such as gangrene, abscess, and fibrosis. How large a part inflammation occupies in the domain of disease is well shown by a cursory reference to any text-book on medicine, in which a large proportion of the space will be found devoted to a description of inflammatory affections, including, amongst many others, bronchitis, pleurisy, pneumonia, pericarditis, gastritis, enteritis, appendicitis, neuritis, myelitis, encephalitis, and nephritis. Now, poisoned plasma is *par excellence* the cause of inflammation; it may, indeed, for all practical purposes be regarded as the sole cause of it, although there may be other contributory factors at work, such as the lowered vitality resulting from sluggish circulation or disturbed nervous action. Many different kinds of blood poisoning may set up inflammation, but the most common are those due to bacterial agency; indeed, the essential purport of inflammation is the destruction of the bacteria, which by the poisons they engender give rise to it. When inflammation occurs independently of bacterial agency, as in gouty bronchitis or the pleurisy of Bright's disease, may it not be because the tissues falsely attribute, as it were, the poisons to a bacterial source?

2. *Degeneration from defective circulation of the plasma.*—Defective circulation of the plasma may be due to central or to local causes. The former include failure of the central pump, and of pulmonary suction which steadily diminishes with advancing years and is therefore largely responsible for the sluggish circulation of the aged. Among the local causes may be mentioned arterial spasm, as in Raynaud's disease, rigidity, narrowing, and blocking of the vessels, inflammation, and disuse leading to lowered functional activity. A good instance of this latter is afforded by the fatty degeneration which takes place in disused muscles: rhythmic contraction of a muscle greatly accelerates the local circulation of blood and lymph, causing the individual muscle cells to be flushed with plasma; on the other hand, when a muscle is at rest the plasma tends to stagnate, and it is not surprising that in these circumstances the muscle fibres should degenerate, the more so that they lack their wonted nerve stimuli.

When a cell is entirely bereft of its plasmic supply it disintegrates and dies, as in the case of the cells poured out into the alveoli in pneumonia, or those forming the contents of an abscess cavity. When, however, the supply of plasma is not entirely cut off but is merely deficient, the cells may

¹ See "Collected Studies of Immunity," by Professor Paul Ehrlich. Translated by Dr. Ch. Boldman. New York, 1906, p. 383.

go on living, for a time at least, but the more highly complex of them tend to degenerate, the amount of degeneration among the different types being in direct proportion to their structural complexity; there takes place, in fact, a struggle for existence among the cells, the more lowly, such as those belonging to the connective tissue, surviving at the expense of the more highly endowed, such as the neurons and the gland cells. This truth is well exemplified by the structural changes observed in passive congestion and in the aged. Chronic passive congestion, as from mitral disease, leads to "brown induration" of the heart, lungs, liver (nutmeg), and other organs and tissues. The tissue plasma in this condition not only stagnates but is altered in composition, owing to the fact that the nutrition of the capillary wall suffers from the sluggishness of the capillary circulation, and this interferes with the proper exudation of the lymph. This altered state of the capillary wall, moreover, allows the formed elements of the blood to pass out in undue quantity. The effect of all this is to cause a considerable alteration in the environment of the individual cells of the tissues, in consequence of which the more highly endowed cells degenerate, some of them dying outright, while the connective tissue hypertrophies, in this way causing considerable induration of the part. Much the same kind of thing happens in the tissues of the aged in whom the plasma is both poor in quality and sluggish in movement. Owing to the unfavourable conditions of nutrition resulting the inferior tissue elements thrive at the expense of the superior; muscle, gland, and nerve cells atrophy and decay and are replaced by the harder connective tissue elements. Hence the tissues lose the softness and succulence of youth.

The time factor in environmental moulding.—In considering the influence of the environment in moulding structure we have to take into consideration the factor of time. Its influence may be thus stated. The longer the moulding agency is in operation the more likely is the resulting structural change to endure—the less likely, i.e., is the cell to revert to the *status quo ante* upon cessation of the moulding influence. This is true both of (a) the changes which are undiscoverable by the microscope and manifest themselves in the functional sphere alone; and (b) of the grosser discoverable changes.

(a) As an instance of undiscoverable modification of cell structure wrought through the environment, that which underlies psychic memory may be cited—e.g., the memory of sounds; the more frequently a tune is heard the better it is remembered, the more enduring, i.e., is the undiscoverable structural change underlying the memory of it. The same truth is exemplified in the case of nervous habits, vicious or otherwise—e.g., the longer a habit spasm persists the more tenacious does it become, the underlying structural basis becoming with every repetition of the habit more and more ingrained. The like is also true of all the functional nervous disorders; thus it is probable that every additional epileptic fit tends to increase the liability to recurrence. And not only nervous but non-nervous habits also tend to get fixed by repetition. When, e.g., through the operation of a specific environmental influence upon it the metabolism of a gland cell has been modified in a certain way, it tends to go on metabolising in the same way after the removal of that influence, and the tendency to do so will be the greater the longer the specific influence has been in operation. It is clear that the basis of this altered metabolic habit is an undiscoverable structural change wrought through the cell environment.

(b) As might be expected, structural alterations sufficiently pronounced to be visible are, as a rule, more likely to persist upon withdrawal of the moulding agency than are undiscoverable changes of structure. The longer the noxious agency has been in operation the more pronounced will the resulting structural change be, and the less the tendency to recovery upon cessation of the noxious influence. This truth is well exemplified in the case of the structural change induced by inflammation. In the slighter and transient forms complete recovery may ensue, the inflamed tissue reverting to the *status quo ante*, but in protracted inflammation, no matter how slight, some permanent structural change is always left.

Though gross structural change in a cell is apt to be permanent, it is surprising to what an extent it may be recovered from. Thus granular, fatty, amyloid, and Zenke's degeneration may all be recovered from, the tendency to recovery being in inverse proportion to the length of time

which the noxious environment causing it has been in operation. Nerve cells may recover from a considerable degree of gross structural change. Thus a nerve cell in which chromatolysis has occurred (e.g., in strychnine poisoning, botulism, or pellagra) may recover entirely; so also may one which has undergone the profound degenerative changes met with in such an affection as diphtheritic neuritis. This is remarkable in view of the extraordinary permanence of those undiscoverable alterations in neuron structure which underlie memory. Not only may these structural changes be far more indelible than the gross structural changes referred to, but they may actually persist in a cell which has undergone gross structural change. Thus, to take a single example, an individual who has recovered from a severe encephalitis may retain the memory of an object seen but once many years before: the single presentation of the object to his organs of vision has left in the cortical cells an impression which has not been effaced by the gross structural changes wrought in the cortex by encephalitis, an impression, too, which has persisted long after those gross changes have disappeared. In respect of this kind of undiscoverable structure nerve cells, indeed, like sex cells, display an extraordinary tenacity, one which may actually resist the influence of environmental agencies capable of effecting gross structural changes in them.

The time factor, then, applies both to discoverable and undiscoverable mouldings. It is necessary to keep this truth in mind in considering the influence of the individual cell environments on growth, development, and decay. The specific plasmic influences which operate upon the component cells of the organism and play such a large part in determining normal development, as well as senile decay, last for years, and the structural changes which they induce are correspondingly deep and enduring. Morbid influences, too, may likewise extend over a long period and produce lasting structural perversions, and if this happens during the years of development it will produce an evil effect which no amount of after care will efface. A delicate boy, though he may under favourable circumstances "grow up into a strong man," cannot attain to that standard which a healthy childman would have rendered possible. Long years of delicacy during the epoch of development inevitably leave an evil impress. These considerations emphasise the importance of impress, promptly checking any morbid environmental influence, plasmic or other, that may be present. It is important to do this at all stages of life, but especially during the developmental period. It is not a matter of indifference whether the error be rectified now or some time hence; we should, if possible, correct it at once, so that no vicious impress be left upon the organism. The principle of *principiis obsta* is an important one for the physician.

We are, I think, too apt to overlook the permanent evil which may result from the less malignant forms of morbid cell environment, such, for example, as that induced by indigestion toxæmia. If this condition is pronounced and if it lasts, as it often does, for many years, how can it fail to impress the tissues permanently, notably such impressionable tissues as the nervous? Suppose the toxæmia to be of a kind apt to produce irritability, depression, and muddle-headedness; then on the principle that functional change implies structural change, does it not follow that a long-continued toxæmia of this kind must necessarily impress the cortical neurons structurally, and that too in an injurious way? Apart from such *a priori* considerations, I am convinced from actual observations that intellectual development may in this way be greatly hampered, and that of two individuals with exactly the same mental potentialities and educated in exactly the same way, the one having a sound digestion, and the other being the victim of chronic indigestion toxæmia causing the mental symptoms in question, the former will far outstrip the latter in mental development.

Summary.—The composition of the plasma varies with every phase of life—infancy, childhood, adolescence, maturity, and old age, and in large measure determines the anatomical changes characteristic of these epochs. Probably many of the grosser anatomical characteristics of race have their origin in the plasma. Excluding short-lived cells, like the chromocytes, and genuine senile degeneration, degeneration never occurs spontaneously in a normally evolved cell, but is always traceable to specific environmental influence.

(To be continued.)

THE REGISTRAR-GENERAL'S SIXTY-EIGHTH ANNUAL REPORT.

III.¹

FURTHER continuing our review of this report we notice that in the course of his final remarks Sir William Dunbar speaks appreciatively of the completion by the Royal College of Physicians of London of the third revision of its Nomenclature of Diseases. This document, the preparation of which has occupied three years, will be welcomed by all who are interested in the progress of scientific medicine and will doubtlessly be serviceable to medical practitioners in their duties under the Registration Acts.

A feature in these reports, which in each successive year since 1901 has attained fuller development, is the collection of vital statistics from our colonies and from the principal foreign countries and their reduction to a common standard for comparison with those of our own country. To these statistics further reference is made when the mortality of particular diseases is dealt with.

Among new departures in the latest revision of the Nomenclature we notice that the great group of general diseases—the *morbi corporis universi* of a previous revision—has been subdivided, the “infections” being distinguished from the “intoxications,” and the other general diseases the nature of which is still uncertain being arranged in lists by themselves. At an early stage of its labours the Royal College of Physicians of London appears to have determined this question of classification, for it was adopted in the new official list of causes of death compiled for the Registrar-General's report for 1901 by Dr. Tatham who availed himself of the information at his disposal as a member of a special committee of the College in order to bring the official list of causes of death into harmony with the authorised classification. Now that the new revision of the Nomenclature has been published it is satisfactory to find that no modification is required of the official list of causes of death in use in the English reports since the beginning of the present century and adopted for their reports by the Registrars-General of Scotland and Ireland.

In this country the mean proportion of deaths registered without attestation by medical men appears to be nearly constant from year to year; but in 1905 this proportion in several of the English and Welsh counties was unduly high, reaching in one county as much as 7.6 per cent. of the total deaths. According, we believe, to ancient custom the causes of deaths certified by coroners after inquest are regarded for registration purposes as sufficiently attested, but it would surely be absurd to contend that the coroner's certificate based on after-death appearances alone is in any sense of equal value with that of a medical man actually in attendance on the patient during life. We are therefore of opinion that in all inquest cases where a medical certificate as to cause of death is attainable that document should accompany the certificate of the coroner for the consideration of the Registrar-General.

Among “general diseases” that are exceptionally destructive to life Dr. Tatham has selected for particular comment three—pneumonia, tuberculosis, and cancer. These diseases in the aggregate are responsible for fully one quarter of the mortality from all causes, and the last two of them are now fortunately under investigation by competent authorities, with the view of discovering, in the one case, the exact nature of the morbid processes involved and, in the other case, the best means for controlling its ravages. Taking one year with another, each million of the English population loses annually about 1300 of its number by pneumonia. The disease is everywhere more fatal to males than to females and much more fatal in the towns than in the country. The age incidence of the several types of pneumonia varies considerably; lobar or croupous pneumonia appears to be especially fatal at ages after the forty-fifth year, whereas catarrhal or broncho-pneumonia, whilst also very fatal after mid-life, is enormously more so among young children to whom it is by far the most fatal form of the malady.

To tuberculosis in one or another of its forms nearly 11 per cent. of the total mortality was referred in the year 1905, the death-rate being equal to 1632 per 1,000,000 of the

population of both sexes. Of the deaths at all ages, one-fifth part took place at ages below five years, the disease being somewhat more destructive to boys than to girls and much more destructive in the towns than in the country.

Of the 1632 deaths from tuberculosis occurring in each million of the English population, as many as 1140 were caused by pulmonary tuberculosis. Presumably because of the havoc made by this malady amongst the bread-winners of the working classes, it is against pulmonary tuberculosis for the most part that hitherto preventive measures have been directed. Even if sanatoriums were more nearly adequate than at present for the needs of the community, it is as yet too early to form an estimate of their influence in reducing the prevalence of this disease. But there is no doubt that, short of actual hospital isolation of the sufferers, the general preventive measures taken by sanitary authorities have powerfully operated in this direction. At any rate, the returns show that the mortality from the disease in question is steadily and not slowly decreasing as one year succeeds another. As in other recent years the present report shows excessive incidence on the male portion of the community, the mortality in 1905 having been higher in males at all ages than in females by fully 40 per cent. In that year, too, the disease showed the usual excess of fatality in the urban over the rural portions of England.

In recent years inordinate mortality from pulmonary tuberculosis has been recorded in parts of Wales. Thus, in the year under notice it appears that of the 12 registration counties constituting the principality there were seven in which the male death-rate from this disease exceeded the average for England and Wales, and ten in which the female death-rate was in excess. Among these counties the highest death-rates were, among males, 2158 per 1,000,000 in Merionethshire and 2075 in Cardiganshire, and among females, 2141 in Cardiganshire and 1659 in Anglesey. As regards the age of maximum mortality from this disease, it is interesting to note that it occurs much earlier in the country than in the towns. In the urban group of counties pulmonary tuberculosis showed in 1905 the greatest fatality at the age 45–55 in men and at 35–45 in women, whilst in the rural county group the maximum age was 25–35 in both sexes.

In attempting to compare English mortality from pulmonary tuberculosis with that of our colonies or of other countries we are met by the difficulty that in some of these the deaths from this disease are not separated in the returns from those due to other forms of tuberculosis. Taking the figures as they stand in the report it would appear that out of the 24 countries therein mentioned 14 show a higher average mortality than our own, the remaining countries, including our Australian colonies and Italy, showing a rate considerably below that of England and Wales.

From cancer or malignant disease the loss of life in England and Wales still continues to show an increase, the deaths of males in 1905 exceeding the decennial average by 13 per cent and that of females by 5 per cent. If the deaths from cancer in 1905 be calculated on the aggregate population of the respective sexes without reference to age the disease will be found to have destroyed 756 per 1,000,000 males living in that year, which is the highest rate hitherto recorded, and to have destroyed 1005 females per 1,000,000 living, a rate which is only a trifle below the rate of 1904, which had been the highest on record. The statistics of 1905 confirm those of previous years in showing that cancer is more destructive to women than to men. This difference may, however, be accounted for by the well-known tendency of the disease to invade quite exceptionally the mammary and generative organs of females. In the last five years the male deaths from cancer, less those in which the mammary and generative systems were involved, corresponded to a rate of 712 per million living, whilst the female rate with the same limitations did not exceed 584 per million.

Among ordinary infectious diseases Dr. Tatham selects two for particular notice, diphtheria and enteric fever, both of which diseases were attended by less than the average fatality in the year under notice. The statistics of fatal diphtheria are still vitiated by the practice unfortunately persisting in some parts of using the terms croup and membranous laryngitis as equivalents for diphtheria, although in respect of the latter term this practice has been forbidden by the Royal College of Physicians of London. Taking diphtheria and croup together, the disease would appear to have shown in 1905 the greatest prevalence in South Wales and

¹ Previous notices of this report appeared in THE LANCET of Feb. 15th, p. 450, and March 2nd, p. 606.

in Lincolnshire, Worcestershire and Rutlandshire showing a favourable record in this respect. The mortality from enteric (or typhoid) fever was lower in 1905 than in any other year on record. Compared with the decennial average the mortality of England and Wales from this disease was lower by 31 per cent. The behaviour of enteric fever in 1905 is, however, remarkable in this respect, that whilst, on the one hand, the urban group of counties experienced a considerable decrease as compared with the average, on the other hand the rural group of counties experienced an increase. This abnormal difference may, however, be explained by the circumstance that a severe outburst of enteric fever occurred in Lincolnshire in the early part of the year.

MEDICINE AND THE LAW.

Water Rates for Medical Men.

AT Watford Dr. S. I. Lightfoot was summoned recently for the non-payment of part of the water rate levied upon him by the Watford urban district council. In addition to the rate of 1s. in the £ for water for domestic use he had been charged 5s. for water used in his garden and 10s. for water used in his dispensary. No agreement as to the water supplied for the two latter purposes had been entered into and Dr. Lightfoot had paid the 5s. rate but had declined to pay the 10s. The Bench decided that in the absence of an agreement to pay the special rate the summons must be dismissed, so that the defendant was successful in resisting the prosecution but was not able to obtain a decision as to whether the water used by him in his dispensary should be covered by the payment made for water supplied for domestic purposes only.

Bill to Abolish the View of the Body at Coroners' Inquests.

Mr. Luke White, who is the coroner for North-East Yorkshire, has just introduced a Bill in Parliament "to dispense with the compulsory viewing of bodies on the holding of coroners' inquests." The Bill is supported among others by Mr. Bramsdon, the coroner for Portsmouth. So far back as 1879 a Coroners Bill was being considered by a Select Committee of the House of Commons which (Clause 5) would have given this relief. Later, in 1898 and 1899, circulars were sent out by the Home Secretary to coroners and their deputies inquiring if the proposed change was in their opinion desirable. In March, 1900, it was elicited from Sir Matthew White Ridley, then Home Secretary, by Mr. John Wilson that a majority of replies to the circular favoured the suggested reform and a very large majority desired some change, but the nature of such change was the cause of a very great difference of opinion. At present "an inquest on the death of man" is void unless the body has been viewed by the coroner, by the identifying witness, and by the inquest jury. The last should not view the body until they have been sworn in, as prior to that they are not a jury. This rule is very often ignored by coroners. In the absence of an identifying witness and where charges of negligence or violence precedent to the death are preferred the inquest jury have little need nowadays to view the body of what in our modern congested civilisation must in most cases be that of an entire stranger. A summary of the history of this ancient custom was given in THE LANCET of Nov. 18th, 1905, p. 1501.

The Overlying and Accidental Burning of Children.

A Bill to amend the Prevention of Cruelty to Children Act, 1904, has been introduced in the House of Commons by Mr. Bramsdon, M.P., and has among its "backers" Mr. T. P. O'Connor, M.P., and Mr. Rufus Isaacs, K.C., M.P. The object of the proposed law is to prevent the overlying of young children by adults sleeping with them in the same bed and also the accidental burnings and scaldings which so frequently result from the absence of a fireguard. It will be remembered that a conference was held towards the end of last summer by some members of the executive committee of the National Society for the Prevention of Cruelty to Children and a deputation of members of the Coroners' Society and of the British Medical Association, at which this subject was discussed and at which the forms which preventive legislation might take were suggested. These were described and commented upon in a leading article in THE LANCET of Sept. 15th, 1906, p. 749.

When the Act of 1904, the amendment of which is now proposed, was first introduced the Rev. Benjamin Waugh tried to get included in it clauses making it "exposure" of a child to leave it alone with an unprotected fire and also the "perilous overcrowding of any infant in bed or the going to bed drunk with any infant." These proposed additions to the law were, however, struck out and the new Bill embodies the proposals made by Mr. C. L. Rothera, the coroner for Nottingham, at the conference referred to, by which the law shall be invoked whenever it shall be proved that death has taken place owing to the causes under discussion. In other words, it is not proposed that the act of taking a child to bed with grown-up persons shall in itself be punishable or the act of leaving a child alone in a room with an unguarded fire, even when injury to the child results, but that if the death of a child shall be proved to have been due to these causes then the neglect involved shall become an offence within the meaning of the Prevention of Cruelty to Children Act, 1904. It has no doubt been felt that the suggestion of possible inquisitorial supervision of the homes of the poor would injure the prospects of a useful measure in Parliament but that none could object to a Bill designed on the face of it to protect lives by punishing those responsible for unnecessary deaths. We can only repeat what we have said before—that industrious, kind-hearted, and sober parents are not likely to be injuriously affected by such a law and that the ingenuity of parents and of manufacturers called upon to meet a new demand should soon provide at a low cost such apparatus as the cots and fireguards required. The amendment of the law is urgently needed in order that it may be possible to punish (with such severity as may be appropriate to the individual case) parents who are not sober, not kind-hearted, and not hard-working, who recklessly fail to provide for the safety of their offspring, and through whose neglect poor little children die premature and painful deaths. There is no fear that our judges, magistrates, or juries will allow undeserved punishment to fall upon fathers and mothers whose children's deaths are due to unavoidable circumstances. All parents and persons having the custody of children, however, will have to consider the risks involved and to take precautions which will diminish not only the number of deaths that now take place but injury, suffering, and ill-health not resulting in actual loss of life. The extent of this suffering may be judged from the fact that in recent years the deaths from the causes indicated have amounted to between 3000 and 4000 per annum.

Looking Back.

FROM

THE LANCET, SATURDAY, March 14th, 1829.

DOUBLE PUPIL IN ONE EYE.

A remarkable case of double pupil was observed by Professor Pacini, of Lucca, in a young man who, in his childhood, had, from an unknown external cause, been affected with chronic inflammation of the left eye, which had left it in the following state:—The external parts of the eye are healthy, the cornea is perfectly transparent, except at its external part, where there is a small pterygium; the pupil is elliptic, the fourth part of a line in height, and one line in breadth, and immoveable even in the strongest light. The upper eye-lid being raised, another pupil, three lines and a half in its largest, and one line in its smallest diameter, is discovered at the upper portion of the iris; it is somewhat directed towards the internal angle of the eye, and likewise insensible to light. The parts behind it are perfectly transparent. The young man is long sighted, and squints, the left eye being constantly turned towards the nose; whenever he looks at an object with both eyes, he sees it simple and distinct; if the healthy eye be closed, and the accessory pupil covered, the object appears confused, but if seen with the superior pupil only, it appears simple and distinct. Whenever he looks with the morbid eye at an object placed before him, he sees its right half only, and that double; in order to see it simple, he is forced to direct the eye towards the external angle, and even then the right half is seen more distinctly and somewhat higher than the other. Objects appear of the same

size, whether seen with the morbid or healthy eye; and continued exertion of the former produces a disagreeable sensation in the interior of the globe, so that he is obliged repeatedly to close the eyelids.—*Journ. des Progr.*

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN 76 of the largest English towns 8236 births and 5605 deaths were registered during the week ending March 9th. The annual rate of mortality, which had been equal to 17·1 and 18·4 per 1000 in the two preceding weeks, declined again to 18·2 in the week under notice. During the first ten weeks of the current quarter the death-rate in these towns averaged 19·5 per 1000, the rate during the same period in London being 19·7. The lowest death-rates in the 76 towns during the week were 8·1 in Hornsey, 10·2 in Wallasey, 10·4 in Northampton, and 10·7 in Ipswich; the rates in the other towns ranged upwards to 25·8 in Norwich, 28·4 in Huddersfield, 28·8 in Merthyr Tydfil, and 30·1 in Bury. The 5605 deaths in the 76 towns showed a decline of 47 from the number returned in the previous week, and included 470 which were referred to the principal epidemic diseases, against 390 and 440 in the two preceding weeks; of these, 205 resulted from measles, 105 from whooping-cough, 69 from diphtheria, 35 from scarlet fever, 33 from diarrhoea, 23 from "fever" (principally enteric), and not one from small-pox. The deaths from these epidemic diseases were equal to an annual rate of 1·5 per 1000 in the 76 towns, the rate from the same diseases being also 1·5 in London. No death from any of these epidemic diseases was registered in Oldham, Huddersfield, Hornsey, Coventry, or in four other of the 76 towns; the annual rate therefrom, however, ranged upwards to 5·2 in Grimsby, 5·3 in West Bromwich, 5·4 in East Ham, and 6·2 in St. Helens. The 205 fatal cases of measles showed a marked further increase upon recent weekly numbers and caused an annual rate of 3·4 per 1000 in East Ham, 4·4 in Grimsby, 5·1 in St. Helens, and 5·3 in West Bromwich. The 105 deaths from whooping-cough were fewer by 12 than those in the previous week, the highest annual rates therefrom being 1·2 in York, 1·4 in Nottingham and in South Shields, and 1·9 in East Ham. The 69 deaths referred to diphtheria showed an increase of nine, and were proportionally most numerous in Derby. Scarlet fever was most fatal in Newport (Mon.), and diarrhoea in Rhondda and Bourne-mouth. The deaths from "fever" showed no marked excess in any of the towns. Cerebro-spinal meningitis caused one death in St. Helens. No case of small-pox has been under treatment in the Metropolitan Asylums Hospitals since the end of June last. The number of scarlet fever patients under treatment in the Metropolitan Asylums Hospitals and in the London Fever Hospital, which had steadily declined in the ten preceding weeks from 3846 to 2878, was again 2878 in the week under notice; 306 new cases of this disease were admitted to these hospitals during the week, against 363, 322, and 326 in the three previous weeks. The deaths in London referred to pneumonia and other diseases of the respiratory organs, which had been 379 and 432 in the two preceding weeks, declined again to 405 in the week under notice, but were eight above the corrected average number in the corresponding week of the last five years. The causes of 55, or 1·0 per cent., of the deaths registered during the week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Bristol, West Ham, Bradford, Newcastle-on-Tyne, and in 44 other of the 76 towns; the proportion of uncertified deaths, however, showed a marked excess in Preston, Sheffield, Hull, Middlesbrough, and Gateshead.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in eight of the principal Scotch towns, which had been equal to 18·8 and 20·3 in the two preceding weeks, further rose to 20·6 in the week ending March 9th, and exceeded the mean rate in the 76 English towns by 2·4. The rates in the eight Scotch towns ranged from 13·2 and 18·5 in Greenock and Perth to 22·4 in Aberdeen and 23·5 in Leith. The 716 deaths in the eight towns showed an increase of ten upon the number in the previous week, and included 112

which were referred to the principal epidemic diseases, against 71 and 98 in the two preceding weeks. These 112 deaths were equal to an annual rate of 3·2 per 1000, which exceeded by 1·7 the rate from the same diseases in the 76 English towns; they included 52 which were referred to "fever," 26 to whooping-cough, 15 to diphtheria, 13 to diarrhoea, six to measles, and not one either to scarlet fever or small-pox. The deaths referred to "fever," which had been 49, 25, and 47 in the three previous weeks, further rose to 52 in the week under notice, and included 32 in Glasgow, ten in Leith, nine in Edinburgh, and one in Dundee; 28 of the 32 deaths from "fever" in Glasgow, seven of the nine in Edinburgh, all the ten in Leith, and the death in Dundee were certified as cerebro-spinal meningitis. The 26 fatal cases of whooping-cough, against 27 and 25 in the two previous weeks, included 21 in Glasgow and three in Paisley. The 15 deaths referred to diphtheria showed a considerable increase upon recent weekly numbers; seven occurred in Glasgow, three in Dundee, and three in Paisley. The fatal cases of diarrhoea were also more numerous, including six in Glasgow, three in Edinburgh, and two in Aberdeen. Measles caused three deaths in Aberdeen and two in Glasgow. The deaths in the eight towns referred to diseases of the respiratory organs, including pneumonia, which had declined from 178 to 124 in the four preceding weeks, rose again to 149 in the week under notice, and exceeded the number in the corresponding week of last year by 24. The causes of 22, or 3·1 per cent., of the deaths registered in the eight towns during the week were not certified or not stated; the mean proportion of uncertified deaths in the 76 English towns during the same week did not exceed 1·0 per cent.

HEALTH OF DUBLIN.

The annual death-rate in Dublin, which had been equal to 31·4, 27·1, and 28·6 per 1000 in the three preceding weeks, declined to 25·2 in the week ending March 9th. During the first ten weeks of the current quarter the death-rate in the city averaged 28·3 per 1000; the mean rate during the same period did not exceed 19·5 in London and 20·0 in Edinburgh. The 189 deaths of Dublin residents registered in the week under notice showed a decline of 25 from the number in the previous week, and included ten which were referred to the principal epidemic diseases, showing a slight increase upon recent weekly numbers. These ten deaths were equal to an annual rate of 1·3 per 1000, and included seven from whooping-cough, one each from measles, diphtheria, and diarrhoea, and not one either from small-pox, scarlet fever, or "fever." The fatal cases of whooping-cough corresponded with the number in the previous week. Four deaths were also referred to cerebro-spinal fever. The deaths in the city included 29 of infants under one year of age and 51 of persons aged upwards of 60 years; both these numbers showed a marked decline from the numbers in the previous week. Three deaths from violence and seven inquest cases were registered; and 73, or 38·6 per cent., of the deaths occurred in public institutions. The causes of four, or 2·2 per cent., of the deaths registered during the week were not certified; the percentage of uncertified deaths in the week under notice was equal to 4·5 in Edinburgh, while it did not exceed 0·2 in London. The 167 deaths registered in Belfast during the week ending March 9th included 21 certified as due to cerebro-spinal meningitis or cerebro-spinal fever.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

THE following appointments are notified:—Staff Surgeon: T. W. Philip, to the *Tyagar*.

ROYAL HORSE GUARDS.

Captain Percival J. Bodington, from the Royal Army Medical Corps, to be Surgeon-Captain, vice St. John B. Killery, who exchanges (dated March 1st, 1907).

ROYAL ARMY MEDICAL CORPS.

Captain J. S. Bostock has arrived at Portsmouth for duty. Major T. B. Beach, from Chatham, has been appointed to the Royal Arsenal, Woolwich, for duty.

Surgeon-Captain St. John B. Killery, from the Royal Horse Guards, to be Captain, vice Percival J. Bodington, who exchanges (dated March 1st, 1907). Captain St. John B. Killery to be Major (dated March 1st, 1907).

Captain F. A. Stephens has been appointed Recruiting Medical Officer at Edinburgh.

ROYAL ARMY MEDICAL CORPS IN INDIA.

The following appointments have been made:—Lieutenant-Colonel T. P. Woodhouse, on being relieved of his present appointment, to command of the Station Hospital, Kasauli. Lieutenant-Colonel R. Holyoake to command of the Station Hospital, Dagshai. Major W. G. Beyts to command of the Station Hospital, Subathu. Lieutenant-Colonel F. J. O'Donnell has returned to Quetta from privilege leave. Lieutenant-Colonel S. Westcott has arrived at Mhow and assumed command Station Hospital there. Captain E. W. Powell has arrived at Poona. Captain T. F. Ritchie has arrived at Aden from the Northern Command. Captain J. P. J. Murphy sailed for England (tour expired) on Feb. 8th. Lieutenant W. Benson, nominated for duty in the Northern Command, has, on arrival in India, been posted to Rawal Pindi. Lieutenant-Colonel H. B. Mathias, D.S.O., has been transferred to Simla for duty at army head-quarters. Lieutenant M. D. Ahern has been transferred from 1st (Peshawar) to the 3rd (Lahore) Division. Leave out of India to following officers has been granted—namely: Major H. W. K. Read, six months; Captain E. S. Worthington, seven months; Captain W. F. Tyndale, six months; Captain D. O. Hyde, six months; and Lieutenant F. H. Noke, six months.

ARMY MEDICAL RESERVE OF OFFICERS.

Surgeon-Captain Alexander Macdonald to be Surgeon-Major (dated Feb. 27th, 1907).

SIR JOHN HARRY KER INNES, K.O.B., SURGEON-GENERAL, A.M.D. (RETIRED).

We regret to announce that this veteran army surgeon, whose record includes distinguished service in the Crimea, the Indian Mutiny, and on the British Sanitary Commission at the German headquarters during the war of 1870-71, is seriously ill from double pneumonia at his residence in Florence. Till lately, in spite of his 87 years, he was one of the most active members of the English-speaking colony in the Tuscan capital, but the influenza, which has been epidemic for the last three months on the Italian Riviera and in the chief inland towns, attacked him early last week and, now that the pulmonary complication has supervened, leaves little hope of recovery.

Correspondence.

"Audi alteram partem."

THE SURGEON'S POWER OF LIFE AND DEATH.

To the Editors of THE LANCET.

SIRS,—I read with interest Dr. J. A. Rigby's verbose and effusive epistle published in *THE LANCET* of Feb. 16th in reply to a leading article which had appeared some weeks previously in your paper. I had not the pleasure or otherwise of reading Dr. Rigby's original contribution to the *Independent Review* so that I am not in a position to criticise it, but many of the statements in his letter appear to me open to criticism. He states "as soon as a man has obtained any medical qualification he is at once given the power of deciding whether a person consulting him shall be submitted to an operation which may cost him his life." Literally that statement is true enough, but practically such a thing seldom occurs. Speaking generally, one finds that a newly qualified man either goes as an assistant in private practice or takes a resident hospital appointment. Now, I venture to assert that few principals will permit their assistants to operate in serious cases, and house surgeons are not, as a rule, allowed to undertake serious major operations. If a man just qualified starts practice for himself, he will not at first have many opportunities of deciding this momentous question. Thus Dr. Rigby raises an alarm in a matter that, practically speaking, never occurs.

I cannot pass Dr. Rigby's remarks on appendicitis without

comment. I think his experience in such cases must be unique, for only to have seen two cases in over 30 years of medical work is remarkable and the people of Preston and district are to be congratulated on their singular immunity from that complaint. He appears to argue that operative interference has not reduced the mortality and that the mortality has been increased by cases unnecessarily operated upon. I do not agree with him. Personally I have seen at least two cases in which death ensued owing to operative interference being delayed too long. Does he advise medical treatment for gangrenous appendicitis with secondary peritonitis? Perhaps such would come under his cases "suitable" for operation, although, in my opinion, the risk is far greater when operation is delayed so long. The mortality in this condition is to a large extent due to cases being handed over to the surgeon when the patients have been poisoned by the toxæmia and when they are in an almost moribund condition. I do not assert that all cases require operation—far from it, for I believe that a large percentage of cases will get well under medical treatment.

Dr. Rigby's bitter tirade against modern surgery is unjust and unfair. I do not agree with everything brought forward by the "advanced" surgeon, but I think his wholesale condemnation of modern methods quite untenable. There is not the least doubt that rapid and progressive development of modern surgery has done much to alleviate human suffering and to save many lives. Dr. Rigby's unjustifiable attack on Dr. Russell has been ably answered by that gentleman himself. I am in perfect agreement with Dr. Russell's remark about the part the physician must play in cases where the surgeon's help may be necessary. The physician should strive to become a skilled diagnostician, but he should take note of surgical advancement, so that he may be able to advise in the interest of his patient, should the assistance of his surgical colleague be necessary. I should like to know if Dr. Rigby advises his patients suffering from cancer to bear up bravely and patiently await death. Or are Preston residents immune from it also? I am not aware of any medicine that will check the progress of cancer, and I believe that the surgeon's knife is the best remedy. If taken early such a procedure affords a means of relief, if not of cure. The skilled physician should endeavour to make his diagnosis early, so that early operation should give the patient a chance of cure. And if relief (as generally happens) only is obtained, is not that worth while?

Dr. Rigby quotes a case in which a gentleman doing an ovariectomy for the first time required some assistance to complete the operation. Truly a most unfortunate spectacle for Dr. Rigby to witness. I should like to know who are to operate in the future if the younger men are not to operate now. Does Dr. Rigby imagine that anyone without experience can do as well as the skilled operator? "Practice makes perfection" is an old saying, and it is only by practice that younger men will attain the requisite skill of their seniors.

Before concluding Dr. Rigby quotes a case from your journal which is irrelevant and immaterial to the discussion and sneers at your journal in publishing such without comment. He evidently believes that your "silence meant consent." I do not think editors as a rule hold themselves responsible for the statements of their contributors and you open your columns for the discussion of that with which you do not agree, as is evidenced by your publication of Dr. Rigby's letter. Everyone is entitled to his own opinion, but I do not think Dr. Rigby will get many of the profession to support him in the majority of his statements.

I am, Sirs, yours faithfully,

J. ALLAN.

March 1st, 1907.

ON THE CONDITION OF THE BLOOD-VESSELS DURING SHOCK.

To the Editors of THE LANCET.

SIRS,—This question is giving rise to a somewhat complicated discussion and I should like to be allowed to endeavour to define some of the points at issue and if possible to throw light upon them. My position with regard to Dr. Crile's views is this. His experiments appear to me to have been arranged and carried out with the greatest skill, ingenuity, and precision. As far as I can judge, all his statements of facts have been proved. He has, however, formulated a theory which I believe to be a mistaken one, and I hold that it can find no secure basis on his facts. I

are propounded a view offering, in my opinion, a better interpretation of all the circumstances, and I have pointed out certain phenomena which I consider to be irreconcilable with Dr. Crile's theory but to be fully accounted for by mine. (satisfactory explanation of any of these difficulties except 17 one has been given. On the other hand, when my theory has been adversely discussed some point concerning facts upon which I fully agree with Dr. Crile has, almost invariably, been selected for criticism.

The letter addressed to you by my friend Dr. Alexander Morison illustrates the state of affairs very well. He holds that I fix my attention too much upon the peripheral circulation. In his view "the cardio-vascular state in shock is one of abased central force accompanied by a simultaneous depression in the neuro-muscular activity of the peripheral circulation."¹ If I had not wished to shorten as much as possible the paper which you were good enough to publish² I would have directed attention, as I did on a former occasion,³ to the fact that I omitted to discuss the important point raised by Dr. Morison because I had no difference of opinion upon it with Dr. Crile. The second statement in Dr. Crile's argument is that the heart muscle is not necessarily enfeebled during shock. He wrote that: "The amount of evidence at hand leads to the conclusion that the heart's action is the last of the great vital functions to fail."⁴ In exact harmony with this I stated six years earlier that "there is reason to believe that death from traumatic fever, from shock, or from pseudo-typhus following laparotomy usually begins elsewhere and not at the heart."⁵ Dr. Crile showed that when the heart's action had been arrested by asphyxia artificial respiration caused it again to act "after a quiescence of as much as 50 seconds in one case."⁶ If blood is adequately supplied to, and taken away from, the heart, the muscular activity of that organ is to a great extent independent and exceedingly persistent. I have myself seen a human heart contracting when all its connexions with the body were severed by a railway injury.⁷

I have examined clinically a number of cases in which the removal of large ovarian tumours caused deep shock, the pulse being hardly perceptible, or quite imperceptible, at the wrist, whilst the heart did not beat quicker than 80 or 90 to the minute, and in one instance was as slow as 48. In this particular patient there was no question of hæmorrhage, the operation being a simple ovariectomy, and in none of these cases was hæmorrhage a marked feature. In such circumstances the immense power of the heart was obvious on feeling the carotids and the heart sounds were loud and distinct. The most definite of these cases were seen when very large, old-standing ovarian tumours were more common than they are now and when the chilling effects of a carbolic spray were added to the depressing influences of the anæsthetic and of the operation. I am quite unable to see any adequate explanation of the phenomena described other than that the vessels were contracted from the periphery up to and including the radials. This view is in accordance with the teaching of every physiologist that stimulation of a sensory nerve causes a contraction of the arteries. I attributed the unusually strong heart action, in part at least, to a cardiac hypertrophy caused by the presence of the tumours and comparable to that found in pregnant women. The condition of some of these patients was so alarming that I am quite sure that neither cardiac acceleration, cardiac excitement, nor cardiac enfeeblement is a necessary accompaniment of severe shock. This view is confirmed by Dr. Crile's observation that "in the experiments in which the cardiac branches of the stellate ganglia had been severed previous to making tests, the heart beat on slowly, and, although death was delayed, it occurred while the heart was beating slowly and regularly."⁸ Such positive evidence may fairly be opposed to Dr. Morison's statement that he has never observed peripheral loss of tension with normal central impulse except in cases of hæmorrhage. Dr. Morison's refutation of one of Dr. Crile's statements of fact, if substantiated, would, of course, cut the ground from under that gentleman's feet as well as from under mine. To

use Dr. Morison's own metaphor, however, I think he will find it possible to shiver a good many lances without making an impression on the facts as Dr. Crile has stated them. Dr. Morison frankly wrote that he had not read Dr. Crile's work.

Dr. Leonard Williams takes up a position exactly comparable to that of Dr. Morison. He wrote in your issue of March 2nd that I had brought forward "nothing of any real importance" to oppose the arguments of Crile, Leonard Hill, E. H. Starling, Lockhart Mummery, and others, who, in his opinion, had made it abundantly clear that "the blood-vessels in shock are dilated and not contracted."⁹ If Dr. Williams had read my paper more carefully and also your report of the discussion at the Royal Medical and Chirurgical Society¹⁰ he would have seen that I quoted Dr. Crile as definitely stating that in deep shock "the arteries were quite empty, the tissues pale, but the venous trunks everywhere were full,"¹¹ whilst Mr. Mummery asserted that as shock developed "all the small arteries could be seen to relax and fill with blood. When surgical shock had been fully established all the arteries, arterioles, and veins could be seen to be relaxed fully."¹² If Dr. Williams had noted these directly contradictory passages I do not think he would have felt justified in asserting that such differences were of no real importance in a discussion on the condition of the blood-vessels during shock. Neither could he have quoted Dr. Crile and Mr. Mummery as holding identical views on this question, for there can be no doubt that in combating my views Mr. Mummery ran a full tilt against those of Dr. Crile. Unless there is some explanation which I cannot now see it is impossible to avoid the conclusion that either Dr. Crile or Mr. Mummery has fallen into an error of observation. When taken together their statements illustrate the extreme difficulty of obtaining facts and prove to demonstration that even experimental work may lead to erroneous teaching.

In the course of abdominal operations I have never seen any sign of a general relaxation of the vessels unless peritonitis or some interference with the circulation existed. Here I would point out that, in his lectures at the Royal College of Surgeons of England, Mr. Mummery said that shock might be induced by exposure of the abdominal viscera.¹³ Such an exposure, if sufficiently prolonged to induce shock, would certainly excite also a peritonitis, in which case exactly those vascular conditions described by Mr. Mummery as characteristic of shock would necessarily be found in the peritoneum. The removal of coils of intestine from the abdominal cavity also frequently involves an interference with the mesenteric vessels and a consequent congestion in the affected coils. But in uncomplicated cases of shock I have always observed, in accordance with the statements of Dr. Crile, that the deeper the shock the more pale and bloodless the tissues became.

I think that in the foregoing remarks I may claim to have shown that my critics are not altogether happy in their arguments if they are to be regarded as supporters of Dr. Crile's teaching. As I understand them they would uphold his theory but will none of his facts. And without doubt the belief that the vessels are fully relaxed during shock is in accord with the conditions which most of us would expect if the vaso-motor centres should break down. Thus the arguments of my opponents seem to me to be strongly in favour of my contention that Dr. Crile's theory can have no sound foundation on his own statements. If it is authoritatively decided that I am in the wrong as regards the points discussed above, some of the most important assertions made by Dr. Crile must also be considered erroneous. His theory if still accepted would then rest on a foundation which is irreconcilable with his expressed views. Surely there is here sufficient evidence to justify my urging the necessity for a reconsideration of this question. I would suggest that if Dr. Crile's view is to be maintained he, or one of his supporters, should categorically explain its relationship to the rise of the specific gravity of the blood and the other phenomena which I have pointed out¹⁴ as being at least difficult to reconcile with it. Failing such explanation, I submit that the physiology and pathology of the condition of the blood-vessels during shock cannot be

satisfactorily founded on Dr. Orile's theory and I would again urge that all the phenomena may be fully accounted for by my view—namely, that the small vessels become tensely contracted as a consequence of traumatism. As the injury increases or is repeated the contraction of the vessels extends from the periphery towards the heart. The superficial vessels are more affected than the deeper ones and thus, as the state of shock becomes profound, the bulk of the blood is transferred from the superficial to the central areas in which the medium-sized and larger vessels yield partly to superior force and partly because of the physiological necessity for conserving heat. As a consequence the blood pressure in the somatic areas is lowered, whilst that in the splanchnic area is raised, exactly as in the process of digestion. A general and extending contraction of all the smaller vessels can in no way hinder a transference of the bulk of the blood from the surface to the centre, nor can it interfere with the relative changes in the blood pressure which necessarily follow. This interpretation removes all the difficulties which I have raised in connexion with Dr. Orile's theory and is in perfect harmony with every statement of fact made by him.

I am, Sirs, yours faithfully,
Portman-street, W., March 8th, 1907. JOHN D. MALCOLM.

HENRY VIII'S BARBER.

To the Editors of THE LANCET.

SIRS,—My attention has been called to a paragraph on p. 604 in your issue of March 2nd entitled "Henry VIII's Barber." Permit me to say that though I did quote the standing order referred to (Harl. MS., 642) as applying probably to Edward IV. or an earlier king I made no reference whatever to Henry VIII. performing "partial ablations on occasional Saturday evenings" or of John Pen being "present at these august ceremonies." The order was undoubtedly obsolete in Henry's time and the mistake has probably arisen through my having stated that Pen held the office of "King's Barber."

I am, Sirs, yours faithfully,
March 7th, 1907. SIDNEY YOUNG.

MEDICAL CANDIDATES FOR THE MASONIC SCHOOLS.

To the Editors of THE LANCET.

SIRS,—May I once again through the medium of your widely read columns appeal to medical Freemasons for their votes and assistance on behalf of the medical candidates up for election to the Masonic schools? At the forthcoming elections there is no medical candidate for the Royal Masonic Institution for Boys, but there are two candidates for the Royal Masonic Institution for Girls (election on April 11th)—namely:

PHILLIS KERSHAW, daughter of the late John Cawthron Kershaw, M.R.C.S. Eng., of Ivy House, 41, Tongue-road, Leeds.
ELIZABETH EDITH SMART, daughter of the late William Pachey Smart, M.R.C.S. Eng., of 270, Monument road, Edgbaston, Birmingham.

In again appealing for votes I would point out that boys' votes are as valuable as those for the girls, because an exchange can always be effected. All votes, either for the girls or the boys, sent to me will be gratefully received and acknowledged by me.

I am, Sirs, yours faithfully,
HAROLD S. SINGTON,

Secretary, the St. Luke's Medical Lodge of Instruction.
Hospital for Sick Children, Great Ormond-street, W.C., March 10th, 1907.

THE MEDICAL PROFESSION AND COMPULSORY MILITARY SERVICE.

To the Editors of THE LANCET.

SIRS,—It is remarkable that Surgeon-General Evatt does not see that compulsory military service of the Swiss type is just what is needed to put an end to the evils the existence of which in our army he so justly denounces. It is obvious that the chief cause of those evils is that the great majority of our soldiers are drawn from classes whose standard of life is not high and which have extremely little social and political influence. If we adopt the Swiss system and all youths, who are physically fit for service, are compelled to

serve together and to receive in their first year of service military training for about three months, the conditions which last year caused 4000 soldiers to go into hospital with itch and 15,000 with ague will at once be changed. Under the new system there would always be some sons and nephews of Members of the two Houses of Parliament serving in the ranks, and, if preventable evils were allowed to injure the health of our soldiers, the Government would hear a great deal more about the matter than it has heard about such evils in the past or hears to-day. And army doctors would find far more intelligent aid in their efforts to improve health in the army from the officers under the new system than they can receive now, when the old taunt, that our army consists of the dregs of the population officered by the froth, has not lost the whole of its point, though happily it is far less applicable than it used to be. The effect on the health of young Englishmen of three months of good physical training, good food, and steady life, in their twentieth year would surely be welcome to Surgeon-General Evatt as well as to all other medical men. The influence of military training on health and strength is so good in Germany and Switzerland that in both those countries the army has been called the Giant Doctor. Far from tightening "the chains of militarism with deadly force on the medical profession," as Surgeon-General Evatt believes it would do, compulsory military service could not fail to make the community as a whole realise, as it has never yet done, that its military system must be brought under the life-preserving influence of the medical profession.

I am, Sirs, yours faithfully,
T. C. HORSFALL,
A Vice-President of the National Service League.
Swanscoe Park, near Macclesfield.

THE FEES OF PUBLIC VACCINATORS.

To the Editors of THE LANCET.

SIRS,—As it appears quite certain that the President of the Local Government Board intends to reduce the fees of public vaccinators I would suggest to any man holding that office that he should write to his Member of Parliament on the subject and say that if the *minimum* fee is to be lowered the work connected therewith should be lessened.

I am, Sirs, yours faithfully,
Cardiff, March 11th, 1907. T. GARRETT HOBDRER.

THE SLAUGHTER-HOUSES AT GIBRALTAR.

To the Editors of THE LANCET.

SIRS,—Will you allow me a little space to make a few remarks on your Special Sanitary Commissioner's report on the slaughter-houses at Gibraltar appearing in your issue of Feb. 23rd, p. 547? Your commissioner in describing the slaughter-houses says that "these consist of a group of low masonry huts that may well have been built a century or more ago." It is evident that there has been some confusion in your commissioner's mind between the low range of buildings in which some of the "offensive trades" are carried on and the slaughter-house itself. This, rather, is a comparatively lofty building of modern construction, well lighted and ventilated, and, as the report states, divided into two parts, used by the civil and military authorities respectively.

I may also add that since your commissioner's visit the military side has been improved by the addition of a well-constructed room for the purpose of storing carcasses of beef, &c. The general sanitary conditions of the slaughter-house at Gibraltar compare very favourably with other establishments of the same size both at home and abroad. No exception can be taken to other portions of your commissioner's article pointing out certain obvious defects of structure and arrangement, but the authorities concerned are not neglectful of these matters and remedial measures are to be carried out this year, the necessary funds having been provided. I trust therefore that it will be seen that some portions of your commissioner's report fail to do full justice to the condition of a building on which the local authorities have spent considerable care and money. My excuse for troubling you with this letter lies in the fact that having recently acted as health officer of Gibraltar for some months

may claim to have a somewhat intimate knowledge of local nity conditions.

I am, Sirs, yours faithfully,

OLIVER L. ROBINSON,
Major R.A.M.C.

Gibraltar, March 7th, 1907.

THE ELECTIONS OF GUARDIANS.

To the Editors of THE LANCET.

SIRS,—In a few days there will be an election of guardians. I impress upon your readers the importance of securing nomination and election of candidates who are in favour of outdoor relief of deserving aged poor where practicable, and of making such out-relief adequate? The local Government Board itself issued a circular to this effect in August, 1900 (which may be bought for 2½d.), and until old age pensions can be obtained this is far better than offering to the veterans of industry a painful choice between the workhouse and starvation or at least great destitution. Also, it is most important to elect guardians who will give outdoor medical relief (in the first instance) to all poor persons unable to pay a medical man, without placing obstacles in the way such as making the relief a loan, or requiring the patient (or in the case of a child, a parent) to appear before the guardians. Of course, when the medical man has seen the patient he can decide whether it is a case to be treated at home or in the Poor-law or some other infirmary or hospital. The great point (for the public health) is to take care that cases of illness come before the medical man at a very early stage. By this means we may check infectious diseases such as measles, whooping-cough, fevers of various descriptions, and phthisis. Cutting down medical relief is dangerous to the public health.

I am, Sirs, yours faithfully,

J. THEODORE DODD,

A Guardian and Councillor of the City of Oxford.

March 12th, 1907.

MANCHESTER.

(FROM OUR OWN CORRESPONDENT.)

Victoria University.

THE acceptance of the office of Chancellor of the Victoria University by the Duke of Devonshire in succession to Earl Spencer, who retired on account of ill-health, has been received with general satisfaction. It may not be remembered by all that the present Duke's father was Chancellor of the University, so that the Devonshire family has taken an active interest in its progress from very early days.

Medical Degrees at the Victoria University.

At a meeting of Convocation on March 6th a communication was received from the registrar relating to the proposed conditions of award of degree of Doctor of Medicine, which had been approved of by the Senate and Council. They had still to be drafted as ordinances and regulations. It was provided, among other things, that—

(1) No candidate will be admitted to the degree of Doctor of Medicine unless he has previously received the degree of Bachelor of Medicine and Bachelor of Surgery; (2) candidates shall produce evidence of having, subsequently to having received the degrees of M.B. and Ch.B., been engaged for at least one year in attendance on the medical practice of a general hospital or on the practice of special hospital or lunatic asylum, or in scientific work bearing directly on his profession such as is conducted in the medical departments of the University, or alternatively of his having been engaged for at least two years in practice other than practice restricted to surgery; and (3) candidates may elect either (1.) to present an original dissertation or (2.) to undergo an examination.

This was accepted and approved.

A Descendant of Hugh Oldham.

Manchester has a strong feeling of regard for its Grammar School, founded in 1515 by Hugh Oldham, Bishop of Exeter, and is interested in the public bequests of the late Mr. Charles James Oldham, F.R.C.S., of Brighton, a descendant of the bishop, chiefly perhaps because he left £3000 to the Grammar School, together with half the residue of his estate, which may amount to from £7000 to £10,000. The legacy of £3000 is "to be applied for the advancement of learning as the authorities may think fit." Another clause in the will suggests that he may not have been altogether free from the prejudices which we sometimes call insular. He "peremptorily requested and desired that no person be appointed as an additional trustee or executor of his will

who shall be either a solicitor, a Jew, or a German, although he may be a British subject, but that he desired rather that a competent business man in a responsible position, such as a bank manager, shall be appointed to such post."

Emergency Cases at Poor-law Hospitals.

At a recent inquest by the city coroner it was stated that a woman was kept waiting in a cab outside the Withington workhouse hospital for 35 minutes when suffering from severe burns from which she died. The jury suggested that provision should be made for the speedy admission of such cases. The clerk to the guardians said that no one could regret more than they did that there should have been such delay, but that the workhouse hospital was under the Poor-law and was purely a pauper establishment for the admission of paupers and not an emergency hospital, such as the Manchester Infirmary and the Ancoats Hospital. In this particular case the medical officer was at the very farthest possible point from the porter's lodge attending to a serious case, and if found at once he would have been some time in getting to the lodge. It must be remembered that the workhouse is a very large establishment. The board has decided to establish a special ward where emergency cases can be admitted at once. It is, no doubt, against the Poor-law theory that non-pauper cases should be admitted but it can easily be understood that the friends of a patient would seek the nearest place where treatment could be obtained.

The New Asylum at Whalley.

The block plan of the asylum at Whalley has received the approval of the Home Secretary and of the Commissioners in Lunacy. The latter body says that the scheme generally commends itself as having advantages in concentration and economy of working. The estimate of the funds required from April, 1907, to March, 1908, amounts to £142,517, and the finance committee of the Lancashire Asylums Board, having regard to the fact that the average weekly cost of maintenance was more than the present charge to the unions, does not think it at present advisable to make any reduction.

March 12th.

LEEDS.

(FROM OUR OWN CORRESPONDENT.)

Appointments at the General Infirmary.

ACTING on the recommendation of the Faculty, the board of the infirmary has appointed Mr. J. A. Coupland surgical registrar in succession to Mr. H. Collinson who was recently elected assistant surgeon in charge of the convalescent hospitals. Mr. Coupland has during the last two years held the position of resident surgical officer at the infirmary and at a meeting of the Faculty held on March 8th Dr. L. R. Braithwaite was elected his successor. Dr. Braithwaite, like Mr. Collinson and Mr. Coupland, had a distinguished career at the Leeds School of Medicine.

The University.

The written examinations for the second M.B., Ch.B. degrees will begin on Monday, March 18th, and that for the first part of the final examination on the same day. In accordance with recent regulations, which direct that Part II. of the final examination shall be held in July and December, there will be no examination in the subjects included in this part of the examination at the end of this term. In future it has been arranged that the examination in Part I. of the final shall also be held in July and December. The *vitæ-vocæ* and practical examinations will follow immediately on the written examinations and the results will be announced on the evening of March 22nd. The work of the term will not end until March 27th and the summer term will begin on April 22nd.

The Association for the Prevention and Cure of Tuberculosis.

A perusal of the seventh annual report of the Association for the Prevention and Cure of Tuberculosis shows that the useful work of this charity is being carried on with continued success and that it is increasing. The total number of patients under treatment during the past year at the sanatorium at Gateforth and at the country hospital amounted to 278, which is an increase of 112 as compared with the previous year. The results of the treatment have been encouraging in many ways. A very useful addition to the accommodation has been made by the provision at Armley Hospital of a Doerker barrack which provides

for the treatment of eight patients. In appealing for an increase in the financial support of the institutions the committee calls attention to the present sources of income. This income amounted during 1906 to only £4097, and this includes a sum of £2000 received under an agreement with the city council whereby the society undertakes the treatment of a certain number of cases. Annual subscriptions are represented by the sum of £1595. The Bradford guardians contribute £122 in respect of the treatment of patients from their union, and the rent, £120, of Arnley House, which is used for the acute cases, is generously contributed by Mr. Henry Barran, a member of the committee. The association possesses no invested funds, and being a charity which deals with a disease which claims in the city almost as large a mortality as all the acute fevers added together—namely, 570 as against 587 deaths respectively for the year 1906—it deserves an amount of support which as yet has not been extended to it.

March 12th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Presentation to Sir Henry D. Littlejohn.

ON March 8th Sir Henry D. Littlejohn, medical officer of health of the city of Edinburgh, was presented with his portrait, painted by Sir George Reid. The movement was initiated when Sir Henry Littlejohn resigned the chair of forensic medicine in the University. The presentation took place in the Royal College of Surgeons, the President of the College occupying the chair. There was a large gathering of representatives of the legal and medical professions, several of the lords of session being present. The presentation was made by Lord Stormonth-Darling who spoke both as an old friend and pupil in appreciative terms of Sir Henry Littlejohn's powers as a teacher and as a medical jurist. Dr. John Smith spoke as his oldest medical friend. Sir Henry Littlejohn in a racy and humorous speech acknowledged the honour which had been conferred upon him.

Admission of Women Dentists.

At the annual general meeting of the Odonto-Chirurgical Society of Scotland it was stated that a new departure had been made in connexion with the society by the admission of lady members. The rules of the society had been modified in order to enable it to welcome them.

Inspection of Imported Meat.

The public health committee of the town council of Glasgow has been considering this week the whole question of the inspection of meat imported into the city from other countries. The question has been raised by the corporation veterinary surgeon, who reported that in the course of his duties on Feb. 18th and again on the 20th he seized as unfit for human food a foreleg of chilled beef deposited in the meat market on the stance of the agent of one of the largest meat exporters in the United States. Each foreleg was marked "U.S. Inspected and passed. 3." On examination each foreleg was found to have the costal pleura stripped from the ribs but at places distinct tuberculous nodules remained and on incision glandular invasion was manifest. These forelegs were parts of carcasses which in accordance with the regulations issued by the Bureau of Animal Industry to the Government meat inspectors detailed for duty in the packing establishments of the United States ought to have been rejected as unfit for human food and to have been used for the manufacture of tallow after the diseased parts had been removed. These two cases seen to indicate that meat inspection in the United States is not so trustworthy as it ought to be. In the report of the Bureau of Animal Industry for 1905 it is stated in dealing with this subject that during the year there were slaughtered in the United States 2,333,879 cattle, 3,346,451 sheep, 6,051,836 swine, or a total of 11,732,165—making the average for each working day 37,482. The number of inspectors is given as 40. It therefore follows that, to overtake the examination of 37,482 animals, each inspector will require to examine the carcasses and viscera of not less than 937 animals each day. This calculation, however, does not allow for holidays or illness, otherwise the number of animals which would fall to be inspected by each inspector would be materially increased.

Another aspect of this subject of meat inspection which has for some time engaged the attention of the Glasgow authorities is the need for a uniform standard of meat inspection throughout the country. In Glasgow the Public Health Act of 1897 dealing with meat inspection is carried out with considerable stringency, but unfortunately authorities outside the city area do not exercise the same thoroughness. The result of this is that many doubtful animals, more especially pigs, rather than be allowed to run the risk of being condemned on reaching Glasgow, are consigned to areas outside the city where they are cured into hams and no doubt ultimately find their way by rail into the city. The only way for the Local Government Board to deal with such a state of matters is to demand a uniform standard of inspection and no doubt the expediency of such a step will come to be recognised in time.

The Girgenti Home for Inebriates.

The corporation of Glasgow has decided to cease taking into the Girgenti reformatory any new inmates; to ask the Secretary for Scotland to arrange for the early removal of all the present inmates to some other inebriate reformatory or to the State reformatory at Perth; and to discontinue at the earliest possible date the use of Girgenti Home as an inebriate reformatory. The institution was started in 1900 at the invitation of the Government to experiment with the new Act dealing with inebriates. A sum of about £3000 was spent in acquiring an estate under the assurance that the Government would practically give the corporation a free hand. No sooner had the property been acquired than the Government interfered and placed a considerable number of difficulties in its way before it was able to open the institution, and after the institution was opened it was found that the Act which it was asked to administer was sadly defective. The Secretary for Scotland could give it no help, as he acknowledged that in the meantime there was no prospect of legislation on the subject. Also, in addition, notice had been received that the Government grant for patients would from April 1st be reduced from 10s. 6d. to 7s. per head. The experiment has cost the ratepayers of Glasgow about £1300 a year, and, although not entirely a failure as many women have been reclaimed, yet it is not sufficiently a success to encourage the ratepayers to carry it on without more support, financial and otherwise, from the Government.

March 12th.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Epidemic Cerebro-spinal Fever in Dublin.

Up to March 12th no additional case of epidemic cerebro-spinal fever has been reported to the public health authorities in Dublin.

Royal National Hospital for Consumption.

The annual meeting in connexion with the Royal National Hospital for Consumption for Ireland was held at the Royal College of Physicians, Dublin, on March 8th. The annual report stated that there had been no further extension of the hospital at Newcastle during the past year. The number of beds is now 100, which was the number originally contemplated when the hospital was founded; they have been fully occupied during the year. The Registrar-General said, in reference to the mortality from tuberculosis in Ireland, that the number of deaths in 1905 was 11,882, representing a rate of 2.71 per 1000 of the population, which means, taking the mortality from the disease in relation to the deaths from all causes, that in every 100 deaths 16 were victims of the malady. As regards tuberculous disease in the Dublin registration area, for 1906 it caused 1694 deaths, representing an annual rate of 4.47 per 1000 of the population. In the registration area the deaths from the pulmonary form of the disease were 1152 in number and represented an annual rate of 3.64 per 1000. Sir Charles Cameron, C.B., said that one of the most potent means of resisting the spread of tuberculosis was the improvement in the dwellings of the working classes. He regretted that out of nine or ten sanitary authorities in the Dublin only three or four expressed agreement with the proposed establishment of a sanatorium. He stated, however, that a sanatorium would be erected in Dublin by the

corporation and the three or four sanitary authorities, even if the others did not join.

The Health Commission in Belfast.

The Belfast Health Commission, which opened its session, as recorded last week, on March 5th, has, in addition to hearing evidence, been personally examining many parts of the city. The members wisely decided at the outset to do all the examining of witnesses themselves, but counsel representing the corporation, the Water Board, and certain of the citizens may, if they wish, put questions to witnesses through the commissioners. The citizens' health committee, which asked for the commission, stated through Sir Charles Brett that it did not require counsel. Its object was to get at the facts in the interests of the health of the city and it would through witnesses help the commission in every way. All those examined so far have been official; they include the Irish Registrar-General, Mr. R. E. Matheson, Dr. J. King Kerr, chairman of the health committee, Mr. H. W. Baillie, superintendent medical officer of health, the chief clerk of the corporation, and the borough surveyor. The members of the commission have impressed the public as a body of able men with special knowledge who are determined to get at the facts, while the revelations that have been made indicate a truly appalling state of affairs in a great city. The chairman of the public health committee preferred to the statistics of the Registrar-General of Ireland deductions of his own, but the official ones will probably be adopted. Those who listened to this evidence and that of the superintendent medical officer of health, and of the city surveyor (who said that not 1 per cent. of the houses in Belfast are separated from the subsoil by concrete or other wholly impervious material) must admit that such things alone proved the necessity for the inquiry. No one—even those asking for the inquiry—imagined that the public health administration of Belfast was in such a deplorable condition. At an official dinner given by the Lord Mayor (the Earl of Shaftesbury) on March 9th, in proposing the toast of "Prosperity to Our City, the City of Belfast," the chief magistrate said, "would that, however, in conjunction with her prosperity she was able to receive a clean bill of health. He could only compare the position of the citizens at that moment, he thought, to a family who had determined to give up an old home and were ready to embark on a new house with all the advantages and conveniences that modern invention could provide. Expert help and advice had been called in and the family, having realised the highest ideal of hygienic surroundings, were satisfied they would adopt and live up to the highest standard of health and order that could be attained."

Epidemic Cerebro-spinal Fever in Belfast.

The "spotted" fever epidemic is increasing in Belfast. On March 11th eight fresh cases were notified in Belfast and the numbers to-day (March 12th) are: notified, 173; and deaths, 94.

The Belfast Samaritan Hospital.

The annual meeting of the friends and supporters of the above hospital was held on March 4th, the Lord Mayor (the Earl of Shaftesbury) presiding. From the medical report it appears that during the year 526 patients were treated in the extern department and 176 patients in the wards. Of the latter, 144 required surgical operation. There were seven deaths, six after operation and one from advanced cancer which was inoperable. Owing to the efforts of the ladies' committee most useful improvements have been made in the hospital which have greatly contributed to the success of the surgical work done in it. Financially the hospital is in debt to the extent of £195, but against this is the fact that at a cost of £356, collected by the ladies' committee, the hospital has been completely renovated, the entire building having been newly painted, new linoleum and furnishing supplied, and the lavatories arranged with the most modern fittings. 310 patients were treated in the extern department with no maternal deaths. There was a large class of students from the Belfast and other schools. Financially, the expenses were nearly £300 in excess of the income of the hospital, but owing to the success of the annual bazaar and other donations, the management had only encroached on the balance in the bank to the extent of £20.

March 12th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Trypanosomiasis in White Men.

ON Feb. 26th M. Laveran read a paper at the Academy of Medicine founded on a report on some researches undertaken by M. Martin. The sufferers from trypanosomiasis had been treated by M. Martin at the Pasteur Hospital and they all came from the French Congo. It is evident from the cases in question that Europeans cannot be considered immune to this serious disease which was formerly considered to affect only the black races. The treatment employed consisted in giving arsenious acid, trypanoth, and, above all, atoxyl. This last drug was given in the form of a one-tenth solution by hypodermic injection. As a rule, a dose of one gramme was given but sometimes 1.50 grammes were given without ill results. Under its influence the trypanosomata disappeared rapidly from the blood but they very soon reappeared if the medicine were not continued. The glandular enlargements and the rashes disappeared as well as the oedema. Despite the great improvement which four of the cases showed and despite the long duration of the treatment M. Martin did not feel at all certain as to a definite cure. On many occasions the treatment was interrupted and all the various troubles, together with the trypanosomata, reappeared. It would seem, then, that atoxyl has a very real efficacy in sleeping sickness, although it cannot be said to be an absolute cure. The best way of administration appears to be by hypodermic injection, and injection into the cerebro-spinal canal does not seem to have any advantage over the hypodermic method. Not more than 0.5 of a gramme should be given to start with, but it may be rapidly increased to one gramme. Injection should be repeated every five days at first and then once in eight days. The action of the atoxyl seems to be directly upon the trypanosomata which can be seen in microscopic preparations as deformed, swollen up, and sometimes in course of investment by the leucocytes. The solutions must not be sterilised at a higher temperature, for this renders the atoxyl less powerful.

The "Oregogenic" Function of the Thyroid Body.

M. Leopold Levi and M. Henri de Rothschild at a meeting of the Society of Biology held on Feb. 16th drew the attention of the society to a function of the thyroid body which they proposed to call "oregogenic"—that is to say, a function of improving the various "appetites." The two observers had already noted 21 cases in which under the influence of an extract of the thyroid body the appetite for food had considerably increased. Since the period of these observations they have been able to collect a number of confirmatory facts. Thyroid extract, besides improving the appetite for food, appeared to them to increase the cerebral activity. Curiosity, power for work, and the desire for study all appeared to be increased. In the following case sexual desire seemed also to be restored. The patient was 37 years of age and suffered from chronic rheumatism with ankylosis and muscular atrophy. He had congenital cataract and suffered from incontinence of urine, chilliness, fatigue, and arterial sclerosis. Administration of thyroid extract ameliorated the rheumatism, increased the appetite for food, and diminished the feeling of chilliness. Sexual desire, which had been absent since 1901, when the patient suffered from exacerbation of his rheumatism, also reappeared. This reappearance corresponds with the favourable influence exercised by the thyroid treatment upon infantilism.

The Purification of Sewage.

At a meeting of the Academy of Sciences held on March 4th M. Muntz gave an account of some researches which he had made together with M. Lainé on the action of peat in purifying sewage. After having ascertained that peat strongly encourages the development of nitrifying bacteria they thought of applying it to the purification of sewage, which really depends upon nitrification. The sewage of large towns and of big industrial establishments is a very real danger to the public health and the system of spreading it on the land gives rise to ill-tasting crops (*c. donné des déboires*). Bacteria beds succeed much better. M. Muntz and M. Lainé have found that peat is extraordinarily active as a nitrifying medium, and that the sewage is purified in a very short time, even in the case of

the most foul examples of the sewage of Paris. Peat, of which there are extensive beds in many departments of France, can thus be considered as an active factor in the war against infection and insanitation.

Hospital Abuse in Paris.

The directors of the Assistance Publique have just issued a poster in the following terms: Advice at hospitals and dispensaries is exclusively intended for the really poor and necessitous. Everyone applying at a hospital must be prepared to prove his identity, to give his domicile in Paris, and to show that he is really poor by a certificate from a *bureau de bienfaisance*, as well as a receipt for his rent. Except in the matter of urgent cases all the medical staff and the other employees of the administration of the Assistance are forbidden to give treatment to anyone whose calling or the amount paid by him in rent appears to make it probable that he is not a fitting subject for hospital treatment. The Assistance will make inquiry into the truth of the statements of patients and if they are found to be abusing the charity the expenses incurred by their treatment will be recoverable by law.

ITALY.

(FROM OUR OWN CORRESPONDENT.)

The Milk supply.

THE full-dress debate on this subject in the Aula della Reale Accademia di Medicina di Turin brought two facts into prominence—namely, the uncleanness with which the cows are milked and the milk itself stored and distributed, and, even more important, the widespread propagation of tuberculosis through the milk of diseased cows. As to the first—the uncleanness—there was evidence given, which the representatives of the dairy interest who intervened in the debate tried vainly to rebut or to minimise, evidence which the English-speaking consumer in Italy may be excused for regarding as a strong deterrent against the use of Italian milk even after every precaution, beginning with boiling, has been put in practice. The methods universal in Italian dairies are little better than mediæval—no insistence on the hands of the milking staff, male or female, being previously cleaned, no washing of the cows' udders, and little or no attention paid to the stalling of the cows themselves, couching as they generally do among their own faecal droppings, amid surrounding conditions offensive to every sense. "Take," said one of the participants in the discussion, "the milk which has been brought to your own house, put it in a flat-bottomed white glass bottle, let it stand for an hour, and then examine the sediment invariably deposited. This, by the usual tests, will be found to be mainly, if not entirely, composed of the faecal droppings in which the cow has been lying, which have accumulated on the udders, and which no attempt at washing the said udders, much less the hands of the milkers, has even partially removed." That fact alone, typical as it is of Italian methods, which are generally more uncleanly the farther south you go, may absolve me from dwelling longer or in minuter detail on the gruesome theme. As to the second fact—the propagation of tuberculosis through the milk of diseased cows—the most striking contribution to the debate was that of Dr. Giovanni Mazzini, professor of sanitary police and veterinary jurisprudence in the Turinese Scuola Superiore di Medicina Veterinaria. Accepting fully the findings of British bacteriologists as to the communicability of the bovine bacillus of tuberculosis to the human subject, Dr. Mazzini proceeded, on the strength of personal investigation, to reinforce the generally received induction that in the majority of cases tuberculosis is transmitted from the cow to man by contagion through the digestive apparatus—transmission by inhalation through the respiratory organs being rare. Infection is most commonly brought about in "prima infanzia," (first infancy) by the bacilli contained in the cow's milk, which, after being swallowed, arrive, through the digestive apparatus, at the lymphatics and so find their way, in due course, through the circulation into the lungs. Sometimes these bacilli are active enough to induce tuberculosis at the infantile stage or at that of puberty; sometimes their pernicious action, thanks to the patient's resisting power, is delayed till much later in life. As to the prevention of

these pathological results Dr. Mazzini, while insisting as emphatically as previous speakers on cleanliness and even on the sterilisation and "pasteurisation" of the milk, would go a step further back and allow no cow to be milked which had not responded satisfactorily to the Behring test as to its immunity from the bacillus tuberculosis. "Three or four cubic centimetres of a solution of crude tuberculin in phenicated water hypodermically injected in a tuberculous cow will raise its temperature from one to two degrees; whereas in a healthy cow the temperature remains unaffected." Such being the case, he would have every milk cow in every Italian dairy subjected to the test by "tuberculinizzazione," the tuberculin being provided by the State gratuitously and the local sanitary authority being charged with the required injections and with the resultant exclusion or admission of the cows. Attempts were made by representatives of the dairy interest to throw doubt on the sufficiency of the test; but Dr. Mazzini, both in the debate and in the subsequent polemic in the journals, professional and lay, succeeded in strengthening his position by reference to experience supplementing his own. From first to last the discussion, conducted with good temper and adequate knowledge, bacteriological and clinical, was creditable to its participants, both of the medical and the veterinary schools, and it will certainly have failed egregiously in its purpose if it does not fructify in legislative intervention for the protection of the public in an article of universal consumption by young and old.

Small-pox on the Frontier.

Imported undoubtedly from France, especially by arrivals from Marseilles, variola of an aggravated form has declared itself in the province of Cuneo. Eight cases (one terminating fatally) have been made public and the next report of the sanitary office is awaited with some anxiety as showing either a diminution or an increase in the epidemic.

Professor Angelo Mosso.

From Syracuse I hear that the Senator Professor Mosso has been for some time in Sicily prosecuting investigations, archaeological and anthropological, into the population of the island in prehistoric times. An ancient Cretan tradition refers to an expedition of Minos into Sicily and of his death at Camico. Among the treasure-trove hitherto discovered there are objects pertaining to the iron age and to the Mycenaean civilisation. Professor Mosso, who holds the chair of physiology in the University of Turin, is a past master in such investigations and his report, expected next summer, is awaited with much interest in Italy and abroad.

March 9th.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

The Study of Medicine by Women.

It was in 1896 that the Minister of Education allowed women to enter the universities of Hungary for the purpose of studying medicine, pharmacy, and law—in fact, everything except theology and technical science. Since that time the number of female students has increased from two to year, so that while in 1896 there were only two female medical students in 1906 their number exceeded 100. The professorial board of the University of Budapest, taking into consideration the small incomes of the male members of the different professions, does not sympathise with the steady increase of the number of female students, and last session Professor Kmety proposed that limitations to the number of female students should be resolved upon. This suggestion, of course, evoked a reply on behalf of the women students, and Dr. Ajtay, professor of legal medicine, will endeavour to smooth away the differences which have arisen.

Vital Statistics.

The Hungarian Academy of Science offers a prize of 1500 kronen (£60) for the best compilation of the statistical data of the last ten years on the subject of fertility as shown by the birth-rate and death-rate.

A Home for Lying-in Women.

The first home for lying-in women will be erected shortly in Budapest from the proceeds of a bequest by the late Manfred Weiss.

The Instruction of Children in Sexual Matters.

A well-supported movement has recently been started in

Budapest in order that children over 12 years of age should be instructed in sexual matters. The movement itself has been subjected to keen criticism on the part of medical practitioners and teachers. Public opinion also seems to be opposed to the idea, although lectures which have been delivered were attended by large audiences.

The Past and Future of Marriage.

Dr. Bólog Somló, the youngest professor of the University of Kolozsvár, recently delivered an interesting address in Nagyvárad on the subject of the Past and Future of Marriage. He spoke of matrimonial life in prehistoric times and followed the various stages as marriage developed from its most primitive form to the present one. He said that once upon a time men captured their wives by force and later they purchased them. Matrimonial life has always had its economic background. He was optimistic with regard to the future of marriage, and thought that the marriages of the future would be much more idealistic than they are to-day.

March 7th.

NEW ZEALAND.

(FROM OUR OWN CORRESPONDENT.)

Working-Class Dwellings.

It would seem that the average colonial idea of the old world workman's conservatism has found its echo here. Quite recently the Government bought land close to each of the large centres—Wellington, Auckland, Christchurch, and Dunedin—and thereon erected dainty dwellings for the working men. Although the architects employed were all of the first rank there has been a great hanging back on the part of the *bonâ fide* workmen. The applications have been few and in some instances have come from the wrong people. While utility and ease of running the house have been conserved, the settlements present a most artistic appearance, because in none of them are all the houses of the same type or pattern. The serried ranks of self-same buildings have been avoided, and for this very reason it would seem that the workman has fought shy of them, more especially in Wellington. Some of the reluctance may have been due to the very elaborate schedule of "don'ts" which were issued, but it cannot be all attributed to this. The new Minister for Labour, the Honourable J. Millar, has gone very carefully into the whole matter and he has in a measure relaxed the regulations with the result that applications have been more numerous. Old fashions die hard and democrats are just as much the slaves of tradition as those whose rule they so desire to alter.

Private Hospitals.

A Bill was passed in the later days of the session dealing with the important matter of private hospitals. Under 1903 no power to regulate such institutions existed. An amendment to the Public Health Act was made and in virtue of this enactment regulations were issued. The control has now been transferred to the hospitals department and the regulations as to the qualifications necessary in the holder of the licence are to be made more severe. The new Act requires that the licensee must be either (1) a medical man; (2) a registered nurse; or (3) a registered midwife.

Regulations affecting Nurses.

It may be well to draw the attention of British nurses to some parts of the law which control the registration of nurses in New Zealand. Very often considerable disappointment is experienced by a nurse arriving from the old country when she finds that, although she may have had hospital training and may have been in practice for some years, she cannot get on the register here. It would seem, judging from the number of applications made, that there are many capable nurses practising in Britain who have not put in three years' training at one individual hospital. They have spent, say, two years at one and perhaps one or more at another, but the Act which is now in force here requires them to have spent *three years at one hospital*. It would be well for all nurses intending to come out to New Zealand to consider carefully whether their educational course has been such as to permit them to register in the colony. The resignation of the assistant Inspector-General of hospitals—Mrs. Grace Neill—marks the close of a departmental career which has been justly termed "excellent." Mrs. Neill was the first lady appointed to this position and since then she

has done a large amount of excellent work. "The Nurses Registration Act" was largely the result of her efforts and the establishment of the State maternity homes may also be credited to her.

New Zealand Branch of the British Medical Association.

A general meeting of the New Zealand branch of the British Medical Association was held in Christchurch on Nov. 29th, 1906, to consider the advisability of registering it under the Unclassified Societies Act. In view of the fact that the parent society is applying for a Royal Charter it was decided to hold over the matter. The next meeting of the branch will be held in March at Dunedin.

Obituary.

The death of Dr. D. MacGregor, Inspector-General of Hospitals and Asylums, removes from New Zealand medical circles one of their most scholarly members. A graduate of the University of Aberdeen and an ardent disciple of Professor Bain he came out to this colony to take up the duties of professor of mental philosophy at the University of Dunedin. During Sir Robert Stout's rule as Premier he was appointed to the charge of the hospitals. He did bold and excellent work with respect to the asylums. Great reforms were necessary but it required a strong man to make them. Dr. MacGregor amply justified the trust reposed in him. He was a scholar, a philosopher, and a most honest man. His fine leonine head, his stalwart figure, and his horror of humbug and hypocrisy in all its forms were the things one remembered after a conversation with him.—Mr. James Martin of Middlemarch was thrown out of his trap between McKae's and Moonlight on Dec. 19th, 1906, and received injuries from which he died. The deceased, who was unmarried and about 54 years of age, was in practice in Dunedin with his brother, Mr. Robert Martin, before he took up his practice at Middlemarch a little over two years ago. The deceased was for some time in West Australia.

The Exclusion of Tuberculous Patients.

Attention has already been drawn to the fact that pulmonary tuberculosis is a notifiable disease here and that also it is one of the diseases which may justify exclusion. That the medical men in Great Britain are unaware of this is evidenced by the fact that nearly every week passengers arrive in Auckland or Wellington and are refused admittance by the health department. Only this week two poor souls arrived by the *Rimutaka* and were refused a permit. To send a man in the last stage of consumption upon a long sea voyage is bad, but to send him to a colony which refuses to undertake his keep and that of those dependent upon him amounts to carelessness bordering on inhumanity. It is unfair to expect that this colony should be made the dumping ground of all the indigent incurables and yet the hardship to the patient is great. No persons in the later stages of the disease are allowed to land, unless they be returning New Zealanders. Only those in the earlier stages who can enter into a satisfactory bond that they can provide for attendance in a private sanatorium are allowed to obtain a footing in the colony.

The Inter-colonial Medical Conference.

Dr. J. M. Mason, chief health officer of the colony, has been appointed president of the sanitary division of the next Inter-colonial Medical Conference which is to be held in Melbourne in 1908.

Wellington, Feb. 6th.

CENTRAL MIDWIVES BOARD.—A special meeting of the Central Midwives Board under the provisions of Rule 4 of the rules of procedure was held on March 7th at Caxton House, Westminster, when Dr. F. H. Champneys was in the chair. The name of Eliza Ashton was struck off the roll, the offence being negligence of certain precautions and failing to advise that a medical practitioner should be sent for. The names of Georgiana Maroh, Sarah London, Eliza Gunter, Elizabeth Forrest, and Hannah Hall were also removed from the roll for similar reasons. Louisa Salmon, Maria Schofield, Mary Muffit, Elizabeth Peat, Elizabeth Langston, Mary Ann Ashton, and Ellen Holmes had their names removed from the roll for not providing themselves with necessary appliances and antiseptics. Sarah Morris and Mary Pitt were cautioned concerning their conduct, they not having sent for a medical practitioner when his attendance was necessary.

the most foul examples of the sewage of Paris. Peat, of which there are extensive beds in many departments of France, can thus be considered as an active factor in the war against infection and insanitation.

Hospital Abuse in Paris.

The directors of the Assistance Publique have just issued a poster in the following terms: Advice at hospitals and dispensaries is exclusively intended for the really poor and necessitous. Everyone applying at a hospital must be prepared to prove his identity, to give his domicile in Paris, and to show that he is really poor by a certificate from a *bureau de bienfaisance*, as well as a receipt for his rent. Except in the matter of urgent cases all the medical staff and the other employees of the administration of the Assistance are forbidden to give treatment to anyone whose calling or the amount paid by him in rent appears to make it probable that he is not a fitting subject for hospital treatment. The Assistance will make inquiry into the truth of the statements of patients and if they are found to be abusing the charity the expenses incurred by their treatment will be recoverable by law.

The Milk-supply.

THE full-dress debate on this subject in the Aula della Reale Accademia di Medicina of Turin brought two facts into prominence—namely, the uncleanness with which the cows are milked and the milk itself stored and distributed, and, even more important, the widespread propagation of tuberculosis through the milk of diseased cows. As to the first—the uncleanness—there was evidence given which the representatives of the dairy interest who intervened in the debate tried vainly to rebut or to minimise, evidence which the English-speaking consumer in Italy may be excused for regarding as a strong deterrent against the use of Italian milk even after every precaution, beginning with boiling, has been put in practice. The methods universal in Italian dairies are little better than mediæval—no insistence on the hands of the milking staff, male or female, being previously cleansed, no washing of the cows' udders, and little or no attention paid to the stalling of the cows themselves, couching as they generally do among their own faecal droppings, amid surrounding conditions offensive to every sense. "Take," said one of the participants in the discussion, "the milk which has been brought to your own house, put it in a flat-bottomed white glass bottle, let it stand for an hour, and then examine the sediment invariably deposited. This, by the usual tests, will be found to be mainly, if not entirely, composed of the faecal droppings in which the cow has been lying, which have accumulated on the udder, and which no attempt at washing the said udders, much less the hands of the milkers, has even partially removed." That fact alone, typical as it is of Italian methods, which are generally more uncleanly the farther south you go, may absolve me from dwelling longer or in minuter detail on the gruesome theme. As to the second fact—the propagation of tuberculosis through the milk of diseased cows—the most striking contribution to the debate was that of Dr. Giovanni Mazzini, professor of sanitary police and veterinary jurisprudence in the Turinese Scuola Superiore di Medicina Veterinaria. Accepting fully the findings of British bacteriologists as to the communicability of the bovine bacillus of tuberculosis to the human subject, Dr. Mazzini proceeded, on the strength of personal investigation, to reinforce the generally received induction that in the majority of cases tuberculosis is transmitted from the cow to man by contagion through the digestive apparatus—transmission by inhalation through the respiratory organs being rare. Infection is most commonly brought about in "prima infanzia," (first infancy) by the bacilli contained in the cow's milk, which, after being swallowed, arrive, through the digestive apparatus, at the lymphatics and so find their way, in due course, through the circulation into the lungs. Sometimes these bacilli are active enough to induce tuberculosis at the infantile stage or at that of puberty; sometimes their pernicious action, thanks to the patient's resisting power, is delayed till much later in life. As to the prevention of

these pathological results Dr. Mazzini, while insisting as emphatically as previous speakers on cleanliness and even on the sterilisation and "pasteurisation" of the milk, would go a step further back and allow no cow to be milked which had not responded satisfactorily to the Behring test as to its immunity from the bacillus tuberculosis. "Three or four cubic centimetres of a solution of crude tuberculin in phenicated water hypodermically injected in a tuberculous cow will raise its temperature from one to two degrees; whereas in a healthy cow the temperature remains unaffected." Such being the case, he would have every milch cow in every Italian dairy subjected to the test by "tuberculinizzazione," the tuberculin being provided by the State gratuitously and the local sanitary authority being charged with the required injections and with the resultant exclusion or admission of the cows. Attempts were made by representatives of the dairy interest to throw doubt on the sufficiency of the test; but Dr. Mazzini, both in the debate and in the subsequent polemic in the journals, professional and lay, succeeded in strengthening his position by reference to experience supplementing his own. From first to last the discussion, conducted with good temper and adequate knowledge, bacteriological and clinical, was creditable to its participants, both of the medical and the veterinary schools, and it will certainly have failed egregiously in its purpose if it does not fructify in legislative intervention for the protection of the public in an article of universal consumption by young and old.

Small pox on the Frontier.

Imported undoubtedly from France, especially by arrivals from Marseilles, variola of an aggravated form has declared itself in the province of Cuneo. Eight cases (one terminating fatally) have been made public and the next report of the sanitary office is awaited with some anxiety as showing either a diminution or an increase in the epidemic.

Professor Angelo Mosso.

From Syracuse I hear that the Senator Professor Mosso has been for some time in Sicily prosecuting investigations, archæological and anthropological, into the population of the island in prehistoric times. An ancient Cretan tradition refers to an expedition of Minos into Sicily and of his death at Camico. Among the treasure-trove hitherto discovered there are objects pertaining to the iron age and to the Mycenaean civilisation. Professor Mosso, who holds the chair of physiology in the University of Turin, is a past master in such investigations and his report, expected next summer, is awaited with much interest in Italy and abroad.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

The Study of Medicine by Women.

It was in 1896 that the Minister of Education allowed women to enter the universities of Hungary for the purpose of studying medicine, pharmacy, and law—in fact, everything except theology and technical science. Since that time the number of female students has increased from year to year, so that while in 1896 there were only two female medical students in 1906 their number exceeded 100. The professorial board of the University of Budapest, taking into consideration the small incomes of the male members of the different professions, does not sympathise with the steady increase of the number of female students, and last session Professor Kmety proposed that limitations to the number of female students should be resolved upon. This suggestion, of course, evoked a reply on behalf of the women students, and Dr. Aytay, professor of legal medicine, will endeavour to smooth away the differences which have arisen.

Vital Statistics.

The Hungarian Academy of Science offers a prize of 1500 kronen (£60) for the best compilation of the statistical data of the last ten years on the subject of fertility as shown by the birth-rate and death-rate.

A Home for Lying-in Women.

The first home for lying-in women will be erected shortly in Budapest from the proceeds of a bequest by the late Manfred Weiss.

The Instruction of Children in Sexual Matters.

A well-supported movement has recently been started in

adapest in order that children over 12 years of age should be instructed in sexual matters. The movement itself has been subjected to keen criticism on the part of medical practitioners and teachers. Public opinion also seems to be opposed to the idea, although lectures which have been delivered were attended by large audiences.

'The Past and Future of Marriage.'

Dr. Bólog Somló, the youngest professor of the University of Kolozsvár, recently delivered an interesting address in agyvarad on the subject of the Past and Future of Marriage. He spoke of matrimonial life in prehistoric times and followed the various stages as marriage developed from its most primitive form to the present one. He said that once upon a time men captured their wives by force and later they purchased them. Matrimonial life has always had its economic background. He was optimistic with regard to the future of marriage, and thought that the marriages of the future would be much more idealistic than they are to-day.

March 7th.

NEW ZEALAND.

(FROM OUR OWN CORRESPONDENT.)

Working-Class Dwellings.

It would seem that the average colonial idea of the old world workman's conservatism has found its echo here. Quite recently the Government bought land close to each of the large centres—Wellington, Auckland, Christchurch, and Dunedin—and thereon erected dainty dwellings for the working men. Although the architects employed were all of the first rank there has been a great hanging back on the part of the *bona fide* workmen. The applications have been few and in some instances have come from the wrong people. While utility and ease of running the house have been considered, the settlements present a most artistic appearance, because in none of them are all the houses of the same type or pattern. The serried ranks of self-same buildings have been avoided, and for this very reason it would seem that the workman has fought shy of them, more especially in Wellington. Some of the reluctance may have been due to the very elaborate schedule of "don'ts" which were issued, but it cannot be all attributed to this. The new Minister for Labour, the Honourable J. Millar, has gone very carefully into the whole matter and he has in a measure relaxed the regulations with the result that applications have been more numerous. Old fashions die hard and democrats are just as much the slaves of tradition as those whose rule they do desire to alter.

Private Hospitals.

A Bill was passed in the later days of the session dealing with the important matter of private hospitals. Under 1903 no power to regulate such institutions existed. An amendment to the Public Health Act was made and in virtue of this enactment regulations were issued. The control has now been transferred to the hospitals department and the regulations as to the qualifications necessary in the holder of the licence are to be made more severe. The new Act requires that the licensee must be either (1) a medical man; (2) a registered nurse; or (3) a registered midwife.

Regulations affecting Nurses.

It may be well to draw the attention of British nurses to some parts of the law which control the registration of nurses in New Zealand. Very often considerable disappointment is experienced by a nurse arriving from the old country when she finds that, although she may have had hospital training and may have been in practice for some years, she cannot get on the register here. It would seem, judging from the number of applications made, that there are many capable nurses practising in Britain who have not put in three years' training at one individual hospital. They have spent, say, two years at one and perhaps one or more at another, but the Act which is now in force here requires them to have spent *three years at one hospital*. It would be well for all nurses intending to come out to New Zealand to consider carefully whether their educational course has been such as to permit them to register in the colony. The resignation of the assistant inspector-general of hospitals—Mrs. Grace Neill—marks the close of a departmental career which has been justly termed "excellent." Mrs. Neill was the first lady appointed to this position and since then she

has done a large amount of excellent work. "The Nurses Registration Act" was largely the result of her efforts and the establishment of the State maternity homes may also be credited to her.

New Zealand Branch of the British Medical Association.

A general meeting of the New Zealand branch of the British Medical Association was held in Christchurch on Nov. 29th, 1906, to consider the advisability of registering it under the Unclassified Societies Act. In view of the fact that the parent society is applying for a Royal Charter it was decided to hold over the matter. The next meeting of the branch will be held in March at Dunedin.

Obituary.

The death of Dr. D. MacGregor, Inspector-General of Hospitals and Asylums, removes from New Zealand medical circles one of their most scholarly members. A graduate of the University of Aberdeen and an ardent disciple of Professor Bain he came out to this colony to take up the duties of professor of mental philosophy at the University of Dunedin. During Sir Robert Stout's rule as Premier he was appointed to the charge of the hospitals. He did bold and excellent work with respect to the asylums. Great reforms were necessary but it required a strong man to make them. Dr. MacGregor amply justified the trust reposed in him. He was a scholar, a philosopher, and a most honest man. His fine leonine head, his stalwart figure, and his horror of humbug and hypocrisy in all its forms were the things one remembered after a conversation with him.—Mr. James Martin of Middlemarch was thrown out of his trap between McKee's and Moonlight on Dec. 19th, 1906, and received injuries from which he died. The deceased, who was unmarried and about 54 years of age, was in practice in Dunedin with his brother, Mr. Robert Martin, before he took up his practice at Middlemarch a little over two years ago. The deceased was for some time in West Australia.

The Exclusion of Tuberculous Patients.

Attention has already been drawn to the fact that pulmonary tuberculosis is a notifiable disease here and that also it is one of the diseases which may justify exclusion. That the medical men in Great Britain are unaware of this is evidenced by the fact that nearly every week passengers arrive in Auckland or Wellington and are refused admittance by the health department. Only this week two poor souls arrived by the *Rimutaka* and were refused a permit. To send a man in the last stage of consumption upon a long sea voyage is bad, but to send him to a colony which refuses to undertake his keep and that of those dependent upon him amounts to carelessness bordering on inhumanity. It is unfair to expect that this colony should be made the dumping ground of all the indigent incurables and yet the hardship to the patient is great. No persons in the later stages of the disease are allowed to land, unless they be returning New Zealanders. Only those in the earlier stages who can enter into a satisfactory bond that they can provide for attendance in a private sanatorium are allowed to obtain a footing in the colony.

The Inter-colonial Medical Conference.

Dr. J. M. Mason, chief health officer of the colony, has been appointed president of the sanitary division of the next Inter-colonial Medical Conference which is to be held in Melbourne in 1908.

Wellington, Feb. 6th.

CENTRAL MIDWIVES BOARD.—A special meeting of the Central Midwives Board under the provisions of Rule 4 of the rules of procedure was held on March 7th at Caxton House, Westminster, when Dr. F. H. Champneys was in the chair. The name of Eliza Ashton was struck off the roll, the offence being negligence of certain precautions and failing to advise that a medical practitioner should be sent for. The names of Georgiana Maroh, Sarah London, Eliza Gunter, Elizabeth Forrest, and Hannah Hall were also removed from the roll for similar reasons. Louisa Salmon, Maria Schofield, Mary Muffit, Elizabeth Peat, Elizabeth Langston, Mary Ann Ashton, and Ellen Holmes had their names removed from the roll for not providing themselves with necessary appliances and antiseptics. Sarah Morris and Mary Pitt were cautioned concerning their conduct, they not having sent for a medical practitioner when his attendance was necessary.

Obituary.

SIR WILLIAM HALES HINGSTON, M.D., LL.D., D.C.L.,
F.R.O.S. ENG.

Sir William H. Hingston, an acknowledged leader of surgery in the Dominion of Canada, died at Ottawa on Feb. 19th, as already mentioned in THE LANCET of Feb. 23rd. He was descended from the original Hingston stock of south Devon and east Cornwall, where "Hingston (Hengist) Down" is a memorial of the victory of King Egbert over the Danes, about A.D. 833. The family has had numerous medical members, especially at Plymouth and Liskeard. An Irish branch of the family was founded by Major James Hingston, who was Commissary-General under Cromwell, and received a large tract of land in the south of Ireland for his services. His descendant, Sir William Hingston's father, was an officer in the old 109th Regiment which was raised in Dublin in the latter part of the eighteenth century and sent out to the American war. Here he saw much service and was wounded in two battles. He died in 1831, leaving a widow with six children, one of whom, then an infant, was the future surgeon, having been born at Hinchinbrook, in the province of Quebec, in June, 1829. His childhood was passed in a wild part of Canada, where hunting and fishing were the chief occupations. Young Hingston was educated at Montreal College and later at McGill College. He came to Europe about 1852 and studied at Edinburgh as well as at Berlin, Paris, and other continental cities, taking the degree of M.D. and obtaining the Fellowship of the Royal College of Surgeons of England. Returning to his native country he devoted himself to surgery, being on the staff of the Hôtel Dieu Hospital, Montreal, of which he eventually became surgeon-in-chief. He was also professor of clinical surgery at the University of Laval and was president of the provincial board of health in 1876 and 1877. He married in 1876 Margaret, daughter of the Hon. D. A. Macdonald, formerly Lieutenant-Governor of Ontario. He took a keen interest in public affairs and was mayor of the city of Montreal from 1875 to 1878. In 1875 he was appointed a Commander of the Roman Order of St. Gregory; he received the honour of knighthood from Queen Victoria in 1895; and was made a Senator of the Dominion of Canada in 1896. In 1895 he published a treatise on the "Climate of Canada and its Relations to Life and Health." When the British Association for the Advancement of Science met in Canada some years ago he was appointed vice-president. He was also successively secretary and president of the Canadian Medical Association.

Personally, Sir William Hingston was tall and handsome and his manner was genial and kindly. He was a Roman Catholic and was highly respected throughout the province. He had several children, one son entering the medical profession.

THE HON. ALAN PERCY HARTY MOLYNEUX
HERBERT, M.D. PARIS.

MANY readers of THE LANCET at home and abroad will learn with regret of the death of Dr. the Hon. Alan Herbert at his residence, 18, Rue Duphot, on March 8th. Dr. Herbert had been ill for a few weeks, having had a cerebral hæmorrhage followed by hemiplegia about a month ago. He was attended throughout by his comrade in the internat of the Paris hospitals, Dr. Labadie-Lagrave. Dr. Herbert was the *doyen* of English practitioners in Paris and on the Continent, and was appealed to by them on many occasions for counsel and assistance. At his death-bed were his sisters, the Dowager Countess of Carnarvon and Lady Gwendolen Herbert, who went to Paris a few days previously. He was 71 years of age. In 1901, when the Hertford British Hospital was made over to the British Government by deed of covenant, Dr. Herbert resigned his position of visiting physician, although up to that date he had faithfully attended the wards and the out-patients since its inauguration in 1871—30 years' service.

The Hon. Alan Percy Harty Molyneux Herbert was a son of the third Earl of Carnarvon and was educated at Harrow and Oxford. He then went to Paris, studied medicine, and in 1865 was appointed to the coveted post of *Internes des Hôpitaux*. He took an apartment to begin practice in the Rue Chauveau-Lagarde, but on the declaration of the Franco-German war a few months later he offered his services once

more as *internes* to help to replace those who had left for the front. His whole professional life was associated with the Hertford British Hospital founded by Sir Richard Wallace. The *Anglo-American Annual* gives the following interesting account of its inception:—

It grew up, so to speak, during the two sieges of Paris, in 1870 and 1871. In its origin, it was an appendage to an ambulance; within a year, it became a distinct and permanent institution. Early in January, 1871, during the most distressing period of the German siege, Sir Richard Wallace opened, for the reception of the sick British poor shut up in Paris, two wards immediately adjoining his hospital for the wounded, in the Rue d'Aguesseau; and at the same place a dispensary where outpatients daily received gratuitously medicine and advice. On the 1st of August, the patients, civil and military, were transferred to a commodious house, fitted up for their reception, at Levallois Perret, where, on the 15th of November, there remained only one wounded soldier under treatment; since his discharge, the Hertford British Hospital has been an institution exclusively for British subjects.

On the 2nd of October, Sir Richard Wallace invited to meet him, at his residence, Falconer Atlee, Esq., H. B. M. Consul; Sir John Ross Cormack, M.D., and the Hon. Alan Herbert, M.D., to receive from him in a more formal manner a communication to the effect that he had resolved to build and endow in Paris a hospital for the medical and surgical treatment of poor British subjects to be called the "Hertford British Hospital" in memory of the late Marquis of Hertford. Sir Richard intimated that as a considerable time might elapse before a suitable site could be obtained and permanent buildings be constructed he had taken as a temporary installation the house, garden and dependencies, No. 5, Route de la Bérole. Sir Richard Wallace at the same time intimated his desire to give the management of the hospital and the appointment of its officers to a committee, consisting of himself, Mr. Atlee, Sir John R. Cormack, and Dr. Herbert, the two latter constituting the medical and surgical staff. The committee of management was forthwith constituted in accordance with Sir Richard's proposition, and with a formal minute to that effect was drawn up and signed by those present. Subsequently, M. Emile Lavasseur was added to the committee. At the meeting of the 2nd of October, when the committee was constituted, Dr. Charles Shrimpton was appointed honorary consulting physician, on the proposition of Sir Richard Wallace. The Hertford British Hospital was—as appears from the preceding statement—definitely instituted on the 2nd of October, 1871, and was opened for the reception of patients on the 15th of November, 1871.

The foundation-stone of the new building was laid by Sir Richard and Lady Wallace on the 24th of August, 1877, the anniversary of the death of the Marquis of Hertford. The opening of the new building for the reception of patients was formally inaugurated by a visit from Lord Lyons, British Ambassador at Paris, on the 16th of April, 1879. On the 4th of June, 1879, their Royal Highnesses the Prince and Princess of Wales and the Princess Victoria made a visit of nearly two hours to the hospital. On that occasion His Royal Highness, at the request of Sir Richard Wallace, named the principal male ward *Albert Edward* and the principal female ward *Alicandra*. In July, 1900, Lady Wallace made over the Hospital to the British Government by deed of covenant and the present committee of management was appointed by H.M. Government. The hospital was then thoroughly cleaned, and the drainage scheme was laid down, the electric light installed, and the ventilation and heating improved, and a well-equipped operating theatre has since been added.

With Dr. Herbert's failing health his practice had necessarily diminished in recent years, but for several decades following the war his popularity and success were very great. He was unsparing of himself to the end and will be as much missed by the poor of Paris as by its aristocratic visitors, many of whom remained his patients. Soon after the war he was made Chevalier of the Legion of Honour and a few years ago he was promoted to the rank of officer.

WILLIAM HENRY PEARSE, M.D., M.R.C.P.,
L.R.O.S. EDIN., L.S.A.

Dr. W. H. Pearse died at his residence, 1, Alfred-place, Plymouth, on March 7th, in his 79th year, after a short illness. Dr. Pearse was born at Launceston, Cornwall, where his father was in practice. He received his medical education at the Universities of Edinburgh and Aberdeen and graduated M.D. of the former university in 1851. In 1852 he was admitted M.R.C.P. Edin.

Shortly after graduating Dr. Pearse was elected medical officer to the Liverpool Dispensary, after which he entered the Colonial Emigration Service and visited Australia. Afterwards he went to India, where for 12 years he was surgeon-superintendent of the India Emigration Service. On retiring from the service about 35 years ago he went to reside at Plymouth and shortly afterwards was appointed on the honorary staff of the public dispensary of that town. When the British Medical Association visited Plymouth, about 30 years ago, he read a paper upon the treatment of pulmonary phthisis and particularly referred to the facilities which Dartmoor afforded for dealing with incipient cases of the disease. In his younger days Dr. Pearse did a noble work amongst the poor at the time of the small-pox and cholera epidemics at Plymouth, taking medical charge of two of the temporary hospitals which were erected in the town. Dr. Pearse, who was extremely popular in Plymouth, took an

active interest in municipal matters and will be much missed in the "Three Towns," where his robust and striking figure was so well known, and much sympathy is felt there with his widow, son, and two daughters. The funeral, which took place at Launceston, was largely attended.

EDGAR LEONARD FARNCOMBE, M.A., M.B.,
B.Ch. Oxon., M.R.C.S. Eng., L.R.C.P. Lond.

THE death is announced of Dr. Edgar Leonard Farncombe, which took place at Chudleigh, South Devon, on March 6th from pneumonia after five days' illness. The son of Mr. Richard Farncombe, a Birmingham medical man, Edgar Farncombe was educated at Malvern, St. John's College, Oxford, and St. Bartholomew's Hospital. He took the diplomas of M.R.C.S. Eng., L.R.C.P. Lond., in 1902 and three years later the degrees of M.A., M.B., B.Ch. Oxon. He had a successful career at St. Bartholomew's Hospital, where he held the posts of house surgeon and extern midwifery assistant in 1902 and 1903 and subsequently acted as resident clinical assistant at St. Luke's Hospital. After filling these appointments he went into private practice and at the time of his death he was in partnership with Mr. H. B. Walters at Chudleigh where he was as universally liked and respected as he had been at his school, college, and hospital. His untimely death at the age of 31 years will be mourned by his many friends who will always remember also his devotion to his profession, a devotion which without doubt cost him his life. Dr. Farncombe had been married but little over a year, his wife being the daughter of Mr. J. B. Manly of Birmingham.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.—The deaths of the following eminent foreign medical men are announced:—Dr. Otto, professor of chemistry and pharmacology in the Brunswick Technical School.—Dr. Roland Stücher, privat-docent of gynecology in the University of Breslau, in consequence of an accident while tobogganing in the Zobtengebirge.

Medical News.

UNIVERSITY OF CAMBRIDGE.—Professor G. Sims Woodhead has been appointed to represent the University on the council of the Lister Institute of Preventive Medicine, in the place of the late Sir Michael Foster.—Dr. G. S. Graham-Smith has been appointed university lecturer in hygiene.—A university lecturer in pathology will shortly be appointed at a stipend of £100 a year. Applications had to be sent to the Vice-Chancellor by March 12th.—Professor Seward, F.R.S., will represent the University at the Tercentenary Festival to be held at Bologna in June, in honour of Ulisse Aldrovandi.—At the congregation on Feb. 28th C. Killick Trinity, was admitted to the M.D. degree.—The following degrees were conferred at a Congregation on March 9th:—

M.B.—J. K. Willis, Queens'.

M.B. and B.C.—J. F. Gaskell, Caius; and I. G. Back, Trinity Hall.

TRINITY COLLEGE, DUBLIN.—At the Final Examination in Medicine in Hilary term the following were successful:—

Part I.—W. E. M. Armstrong, Oliver Gogarty, William A. R. Speng, Alfred H. Smith, John C. Baker, and Robert de C. Wheeler.

FOREIGN UNIVERSITY INTELLIGENCE.—*Bern*: Dr. Fritz de Quervain, privat-docent of Surgery, has been granted the title of Professor.—*Bordeaux*: Dr. Lande has been appointed Professor of Forensic Medicine.—*Göttingen*: Dr. Wilhelm Weber, privat-docent of Mental Diseases, has been granted the title of Professor.—*Heidelberg*: Dr. P. Ernst of Zürich has been appointed Professor of Pathological Anatomy and of General Pathology in succession to Dr. J. Arnold, resigned.—*Lourdain*: Dr. Vanderschueren has been appointed Professor of Ophthalmology in succession to the late Dr. E. Venneman.—*Munich*: Dr. Küster, Director of the Surgical Clinic, is about to retire.—*Pavia*: Dr. Giuseppe Frattini has been recognised as privat-docent of External Pathology.—*Prague (German University)*: Dr. Oswald Richter has been recognised as privat-docent of Anatomy and Physiology.—*P...*

Afranio Peixoto has been appointed Extraordinary Professor of Hygiene and Forensic Medicine.

At the general meeting of the Architectural Association, to be held at 18, Telford-street, S.W., on Friday, March 22nd, at 7.30 p.m., a paper will be read by Mr. Edwin T. Hall, Vice-President R.I.B.A., on Sanatoriums. It will be illustrated by many lantern slides and drawings lent by architects abroad.

UNIVERSITY OF DURHAM.—The members of the Convocation of the University have been invited by the Senate to a conference to be held in the Castle Hall of the University at Durham at 2.30 p.m. on March 20th, for the purpose of discussing the Draft Act for the Re-constitution of the University of Durham. Copies of this Draft Act may be obtained by any graduate on application to the Registrar, the University, Durham, or to the Secretary, Armstrong College, Newcastle-upon-Tyne.

THE MEDICAL SOCIETY OF LONDON.—The 134th anniversary dinner of the Medical Society of London was held at the Whitehall Rooms, Hôtel Métropole, on Wednesday last, March 13th. Professor T. Clifford Allbutt, in the unavoidable absence of the Bishop of Ripon, proposed the toast of "The Society," and in the course of his speech referred to the evolution of clinical, or bedside, research as an indispensable means of advancing medical knowledge. This, he said, must always be the criterion of the science of medicine. He also referred to the advantages which would be derived from the establishment of a Ministry of Health in England, separate from the existing complex and irresponsible organisation which existed. The President of the society, Mr. G. A. Ballance, in an eloquent speech, replied for the society. Dr. J. A. Osmered proposed the toast of "The Guests and the Kindred Societies," which was responded to by the Right Hon. Sydney Buxton, M.P., Postmaster-General, Sir Thomas Smith, Mr. J. Warrington Haward, President of the Royal Medical and Chirurgical Society, and Alderman and Sheriff T. B. Crosby, M.D. Sir Lauder Brunton proposed the toast of "The President of the Society" and Dr. F. de Havilland Hall gave that of "The Secretaries and Other Officers."

LEICESTER INFIRMARY EXTENSION: THE NEW EAST WING.—On Feb. 27th the Duke of Rutland, who was accompanied by the Duchess, laid the memorial stone of the new east wing in the presence of a large and representative gathering. Successive mayors of the borough have since 1856 been raising funds for extending the usefulness of the institution and the new wing marks another step in that direction. The original idea was to remodel the wing but the architects strongly advised that the wing should be entirely rebuilt. The new block is separated from the existing buildings by cross-ventilated lobbies, carried on bridges, which will allow of a free circulation of air between the wing and the other buildings. The new wing will provide accommodation for 99 beds, but pending the building of a nursing home will be set apart for the use of the nurses. The accommodation at first will therefore be for 65 beds. Each ward is planned in a similar manner. They will each contain 30 beds, with a window between each bed. In the centre of the wards there will be two small wards for two beds and one bed respectively, together with nurses' room, bathroom, linen room, patients' clothes room, clinical room, ward kitchen, and sanitary annex. At the south end of the larger wards provision is made for two sanitary annexes, one containing bath and lavatories and the other the nurses' work-room with the necessary conveniences. These annexes, it should be explained, are separated from the ward by a cross ventilated lobby carried on a bridge. There will be a bed lift from the basement to the top of the building and on the ground floor a verandah will run the whole length of the west side of the ward, thus enabling beds to be wheeled on to it from the ward. Verandahs will also be erected on each floor and the south end of the other wards. The heating arrangements will be an extension of the present vapour system, assisted by open ventilating stoves. The new wing when completed will cost £12,000. Donations have already been received amounting to over £26,000, this sum including £500 given by Mr. Samuel Odames, for many years a governor of the institution, whose generous gift was in celebration of his eighty-fourth birthday. The board of governors, thus having more than sufficient money to meet its needs, is now in a position to consider the

home in proximity to the infirmary at an estimated cost of £20,000. For the last few years the nurses connected with the institution have been housed on the outskirts of the town at a private residence leased for the purpose. The Duke of Rutland was presented by the architects, Messrs. Everard, Son, and Pick, with a silver trowel bearing the Rutland coat of arms. The mallet used by his Grace was presented by the contractor, Mr. James Chapman. At the conclusion of the proceedings a luncheon was given by the Mayor and Mayoress (Sir Edward and Lady Wood), the company numbering nearly 250.

PRESENTATIONS TO MEDICAL PRACTITIONERS.—On Feb. 12th Mr. John King, L.R.C.P. Edin., M.R.C.S. Eng., was entertained at a complimentary dinner by the Court Stamford Lodge of Foresters, Stratton (Cornwall), and was afterwards presented with a silver flower bowl on an ebony stand, bearing the following inscription: "Presented to John King, Esq., M.R.C.S., L.R.C.P., by the members of Court Stamford, A.O.F., on his retiring from the medical officership of the court, after 41 years' faithful and efficient service. Stratton, February, 1907."—On Feb. 23rd Mr. Gay Wotton Miller, L.R.C.P. Lond., M.R.C.S. Eng., of Pinhoe, Devon, was presented with a silver tea kettle, suitably inscribed, as a mark of respect and esteem by friends and patients in Pinhoe, Broadclyst, and Poltimore on the occasion of his leaving the district.

ROYAL DENTAL HOSPITAL OF LONDON.—The annual general meeting of the governors of this hospital was held on March 14th, Mr. William H. Ash being in the chair. The report of the committee of management showed the continued usefulness of the institution. The number of patients during the year was 27,693, their attendances being 53,505. The committee was pleased to be able to report a further increase in the annual subscriptions which it regarded as an important addition to the assured income of the hospital, while it was evidence of the interest taken by the public in the work in which the committee was engaged. During 1906 the hospital will complete the fiftieth year of its existence and a proposal to issue a special appeal during its jubilee year was under consideration. The committee was pleased to report that to a great extent through the aid received from legacies during the year and the liberality of the governors all the outstanding liabilities, including the debt (mentioned in the last report) of £1150 to the bankers, had been paid, but it regretted that the year wound up with liabilities due to bankers and tradesmen of a sum of £769. The hope was earnestly expressed that funds would soon be forthcoming to discharge these liabilities and also the fixed yearly payment of nearly £3000 to the Prudential Assurance Company, representing the interest on mortgage and part repayment of loan.

LONDON INTER-COLLEGIATE SCHOLARSHIPS BOARD.

—A combined examination for entrance scholarships and exhibitions tenable at University College, King's College, and the East London College will be held in London by the London Inter-Collegiate Scholarships Board on May 14th and following days. The competition, except for five of the scholarships, is limited to those who have not previously been students at any one of the colleges. No competitor can be elected to more than one scholarship or exhibition. All candidates must have passed the matriculation examination of the University of London, or must furnish some other evidence of having had a sound general education. Some scholarships are open to men only, some to women only, and others to men and women. Successful candidates will be required to enter the College by which they are elected in the October following the examination and to pursue a course of study approved by the authorities of the College. Application should be made to the secretary of the London Inter-Collegiate Scholarships Board, University College, Gower-street, London, W.C., for forms of entry, which must be filled in and returned together with a certificate of age and one of good conduct from the principal of the candidate's last school or other satisfactory reference not later than May 1st. The scholarships and exhibitions offered are as follows:—1. At University College four scholarships of £30 each in classics, modern languages, English history, mathematics, physics, chemistry, and elementary biology or botany. 2. At King's College five exhibitions and two scholarships (of different value, from £20 to £50 each) in classics, science, engineering, and arts. 3. At the East London College six

science scholarships and four arts scholarships, all of £40 each. For further particulars regarding the conditions of award, tenure, and payment application should be made to the secretary of the board, Mr. Alfred E. G. Atcoe, University College, Gower-street, London, W.C. For particulars of the work of the colleges at which scholarships are tenable application should be made to the respective college secretaries. The total value of the scholarships is over £1500.

THE ASSOCIATION OF CERTIFICATED DISPENSERS

—This association, which was founded a year ago, held its annual meeting on Feb. 23th at the Apothecaries' Hall, Water-lane, Blackfriars, London. The assistants to the apothecaries derive their status from the Apothecaries Act of 1815 and must not be confused with the Court of Assistants of the Worshipful Society of Apothecaries. During the meeting the secretary, Mr. A. Howell, in his report gave an account of the origin of the assistants' qualification and mentioned that an effort was to be made to introduce a Bill in Parliament for powers to alter the title of assistants and to improve the educational requirements of the candidates. Dr. F. S. Toogood then gave an address upon the Status of the Apothecaries' Assistant, in which he pointed out that in the dispensing of medicines for hospitals, infirmaries, and for private medical practitioners' dispensaries, no qualification as evidenced by certification after examination is required by law. He added that the Local Government Board and other public bodies had issued memoranda stating what certificates they were prepared to accept as evidence of proficiency and among these certificates the parchment granted to an assistant by the Apothecaries' Society figured. He urged upon the association the necessity of securing full recognition of this certificate and to be prepared to guard it against attacks from other certificate-granting bodies.

MANCHESTER EYE AND EAR HOSPITAL.

—This hospital was conducted at 25, St. John-street, Manchester, for nearly 20 years by the late Dr. David McKeown with a lay committee. Dr. McKeown died recently and a body of trustees who hold funds given specifically to this hospital for its particular work decided that the hospital should be carried on in the same manner as the other public hospitals of Manchester and have since elected two honorary aural surgeons and two honorary ophthalmic surgeons. These gentlemen before their appointment were assured by the trustees that certain conditions referring to the conduct of the hospital and the publication of proper reports and accounts would be fulfilled. The names of those appointed were, as honorary ophthalmic surgeons, Dr. Griffiths Apthorn and Mr. G. Aubrey Jelly; and as honorary aural surgeons, Dr. J. A. Knowles Renshaw and Mr. F. H. Westmacott. A medical officer and anesthetist will also be appointed to assist the honorary staff. In 1906 12 beds available for patients were almost continuously occupied, while the out-patient department had an attendance of 20,613, which included 2654 new cases. The accounts of the hospital are being audited and a provisional committee is being formed. The new constitution of the hospital will be announced at a public meeting the date of which will be notified in the public press. It is intended to establish a system of post-graduate clinical instruction and medical men are invited to visit the hospital at any time during the hours of attendance of the staff. Mr. Westmacott is the chairman of the medical board and Mr. J. D. Sutcliffe is the honorary treasurer and chairman *pro tempore*.

SIXTH INTERNATIONAL DERMATOLOGICAL CONGRESS.

—The Sixth International Dermatological Congress will be held from Sept. 9th to 14th at the Academy of Medicine, 17, West 43rd-street, New York, under the following regulations:—1. The meetings will be open to the public. 2. Any member of the medical profession in good standing may become a member of the Congress by registering with the secretary-general at the time of the meeting or previously, or with the secretaries of the respective countries. The fee for membership shall be five dollars (£1), payable to the secretary-general in New York or to the foreign secretaries. 3. Papers should be presented in writing in the English, French, German, Spanish, or Italian languages, and may be discussed in the language most familiar to the speaker. 20 minutes will be allowed to each person selected to present the questions proposed by the committee, and ten minutes to readers of voluntary papers. Five minutes will be granted to any member for discussion of papers. Members desiring to

esent papers should announce to the secretary-general the date before May 1st and should send an abstract of the same to him before that date. A full copy of every paper presented should be given to the secretary of the session immediately after it is read. 4. Precedence in debate will be given to members who announce beforehand their desire to take part in it. Papers will be presented in the order as given on the official programme. 5. The proceedings of the Congress will be published, and each member will be entitled to a copy. 6. Clinical sessions will, on certain days, precede one for the presentation of papers, at which proper time will be allowed for the formal discussion of important cases. Time will also be allowed for the exhibition of drawings, paintings, photographs, models, microscopical demonstrations, and apparatus relating to dermatology. The subjects for discussion already arranged for are: (1) The Etiological Relationship of Organisms found in the Skin in Exanthemata; (2) Tropical Diseases of the Skin; and (3) (a) The Possibility of Immunisation against Syphilis, and (b) The Present Status of Our Knowledge of the Parasitology of Syphilis. A full programme will be sent in June to all who accept membership or who signify their intention to attend the Congress; also details concerning transportation, registration, &c. Any further information may be obtained from Dr. John A. Fordyce, Secretary-General, 80, West 40th-street, New York City.

NATIONAL HOSPITAL FOR THE PARALYSED AND PILEPIC.—Sir Edgar Speyer presided on March 11th at the annual dinner of this hospital, which was held at the Hotel Métropole, London. In proposing "Success to the hospital," the chairman pleaded for funds to carry on the work of the institution. The annual cost of maintenance was £17,000 and the sum needed to be raised every year for benefactions was £12,800. Owing to failure in receipts for legacies, which in 1906 were much below the average, the hospital had to borrow £4000 to make up the shortage between income and expenditure. It was urgently necessary to repay that sum and thus to enable the board of management to maintain the work at its existing level. This toast was acknowledged by Mr. F. Macmillan. Sir Victor Horsley then submitted the toast of "Success to the Nervous Diseases Research Fund." This fund was founded by the board of management to promote and to carry on research into the origin and cure of diseases of the nervous system. Sir Victor Horsley referred to the enormous importance of the study of the bacteriology of nervous diseases, in which branch of science the National Hospital was leading the way. Other speakers were Mr. J. Danvers Power, Sir John Paget, Sir William R. Gowers, and Sir Felix Semon.

UNIVERSITY OF OXFORD.—The Vice-Chancellor of the University of Oxford has received from the Master and Fellows of the College of the Great Hall of the University, commonly called University College in the University of Oxford, a communication to the effect that they have determined to establish and to award a prize for the furtherance of medical science in the University to be known as "The Radcliffe Prize." The prize shall be of the value of £50. It shall be awarded every second year alternately with the Rolleston prize, provided a sufficiently deserving memoir be submitted for adjudication, by the Master and Fellows of University College at their stated general meeting on March 20th for research in any branch of medical science, comprised under the following heads: Human anatomy, physiology, pharmacology, pathology, medicine, surgery, obstetrics, gynaecology, forensic medicine, and hygiene. The prize shall be open to all graduates of the University who shall have proceeded, or shall be proceeding, to a medical degree in the University. Candidates shall not have exceeded 12 years from the date of passing the last examination for the degree of Bachelor of Arts, and shall not, at the date of application, be Fellows on the foundation of Dr. John Radcliffe. Candidates shall send in their memoirs to the Secretary to the Boards of Faculties on or before Dec. 1st in the year preceding the date of the award. The judge shall be appointed by the Board of the Faculty of Medicine and shall act together with the Regius professor of medicine, or a deputy appointed by him, and with a judge appointed by University College. The judges may call in an assessor or two assessors. They shall report to the Master of University College and to the Board of the Faculty of Medicine on or before March 1st ensuing. No memoir

for which any University prize has already been awarded shall be admitted to competition for the Radcliffe prize, and the prize shall not be awarded more than once to the same candidate. The Board of the Faculty of Medicine shall cause to be published in the usual manner due notice (1) of the date for sending in the competing memoirs, and (2) of the conditions of the award; and the Board shall have power on any such occasion to announce that the prize will on that occasion be awarded for research in some particular branch, or branches, of medical science, as above enumerated, provided that such preference be not given to the same subject more than once in any three consecutive competitions. The above regulations notwithstanding, the first award shall, if possible, be made at the stated general meeting of the Master and Fellows of University College on Oct. 28th next ensuing, and the competing memoirs shall be sent in to the Secretary to the Boards of Faculties on or before June 1st, 1907.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Royal Commission on Sewage Disposal.

THE Civil Service Estimates for the year 1907-08, which are now published, show the sums which the Government has allocated to various temporary commissions, committees, and inquiries. A sum of £4687 is put down for the expenses of the Royal Commission on Sewage Disposal. This is the same amount as it received in 1906-07. This Commission has made several reports of an elaborate nature, one of them dealing with the dissemination of disease by means of contaminated shell fish and other evils caused by the discharge of unpurified sewage and trade effluents into tidal waters. The systematic investigation of a number of artificial processes of purifying sewage for the purpose of ascertaining their relative value in different circumstances has, according to the statement in the Estimates, now been completed. The report of the whole of this work is now in a forward state and the Commission hopes to present it in the course of a few months. The Commission has not been appointed for any definite period and it is impossible to state yet when a final report on the questions submitted to it will be made. Some of these questions can only be properly determined after careful and prolonged scientific research.

The Royal Commission on Tuberculosis.

For the needs of the Royal Commission on Tuberculosis a sum of £5664 is set down in the Estimates of 1907-08. This amount is £735 lower than the estimate of 1906-07. It is estimated that £7673 will be required in the coming year for scientific investigations, including the expenses of the experimental farms, buildings, and laboratories, and the remuneration of scientific experts. The Royal Commission on Tuberculosis was appointed in 1901 to inquire with respect to tuberculosis, whether the disease in animals and man is the same, whether animals and man can be reciprocally infected with it, and under what conditions, if at all, the transmission of the disease from animals to man takes place. In February the Commissioners issued a second interim report dealing fully with the work that had been done since the commencement. An appendix to this report, in four volumes, containing details of the experimental work is now in the press and will be issued as soon as it is ready for publication. The Commission was not appointed for any fixed period and it is impossible to say definitely when it will be in a position to give a final answer to all the terms of the reference.

The Royal Commission on the Care of the Feeble minded.

The members of the Royal Commission on the Care and Control of the Feeble minded hope that their labours will be finally completed by the end of June next. The estimate of £393 is based on this assumption. In the year 1906-07 a sum of £4306 was set apart for the expenses of this Commission. Of that amount £260 were put down under the heading of remuneration to medical investigators. Nothing is provided for this purpose in the new Estimates. A brief survey of the work of the Commission is given in a note to the Estimates. It is stated that the Commission was appointed in September, 1904, and the first sitting was held at the end of the following month. The reference to the Commission was extended on Nov. 2nd, 1906, to inquire into the constitution, jurisdiction, and working of the Commission in Lunacy and of other lunacy authorities in England and Wales, and into the expediency of amending the same or adopting some other system of supervising the care of lunatics and mental defectives and to report as to any amendment in that law which in its opinion should be adopted. Up to the date of the extended reference 51 meetings of the Commission were held and 201 witnesses were examined. Since the date of the extended reference, 12 meetings have been held and 35 witnesses examined. Some of the Commissioners

have visited America, Holland, Belgium, France, Germany, Switzerland, Scotland, Ireland (twice), and numerous institutions in England and Wales. Medical investigations have been carried out by specially appointed medical men into the statistics of feeble-minded and defective persons in Manchester, Birmingham, Hull, Glasgow, Stoke-on-Trent, Lincolnshire, Nottinghamshire, Durham, Carmarthen, Carnarvon, Somersetshire, Wiltshire, and four districts in Ireland.

The Royal Commission on Vivisection.

For the Royal Commission on Vivisection the Estimates set apart £1058 for the year 1907-08. This Commission was only appointed in September last and as over a hundred witnesses have already applied to be heard the inquiry may be expected to last for the whole, or nearly the whole, of the financial year 1907-08.

The Education (Provision of Meals) (Scotland) Bill.

Mr. SINGLAIR, the Secretary for Scotland, on Tuesday received a deputation representing the school boards of Edinburgh, Dundee, Leith, and several other smaller Scottish towns, who protested against Parliament passing such a Bill as the Education (Provision of Meals) (Scotland) Bill because it placed the feeding of school children on the rates. After hearing the views of the deputation, Mr. SINGLAIR suggested that a committee should confer with Mr. SMITH, the permanent head of the Scottish Education Department, with the object of overcoming some of their objections to the Bill. This course was adopted.

Deaths from Starvation.

On the motion of Mr. TALBOT a return has been granted by the Local Government Board showing the number of deaths in the Administrative County of London in the year 1906 upon which a coroner's jury has returned a verdict of death from starvation or death accelerated by privation.

Salaries of Medical Officers of Health.

Mr. JOHN BURNS has promised Sir JOHN DICKSON-POYNTER a return showing the salaries of the medical officer of health and of the inspector of nuisances employed by each of the rural district councils in three English counties to be selected. The return will also show the number of cases in which a rural district council in any of the three selected councils has obtained under the Local Government Act, 1888, from the county council, out of the Exchequer contribution account, payment of half the salaries of its medical officer and its inspector of nuisances.

HOUSE OF LORDS.

THURSDAY, MARCH 7TH.

Public Health Legislation.

The Earl of Onslow addressed a question to His Majesty's Government whether in its opinion the time had not arrived for further general public health legislation. He said that since 1890 there had been no general Act dealing with police and sanitary matters, with the exception of some legislation which dealt with isolation hospitals and infectious diseases. However, there were a number of local authorities which had desired to obtain further powers than those given in the general Act. The result was that fresh clauses were brought in, in private Bills dealing with these matters. These clauses might, he thought, be embodied in a Public Health Act which might be applied to those parts of the country where the local authorities were desirous of adopting it. In the three years 1903-06, there had been a clause prohibiting persons suffering from an infectious disease from personally carrying on a business introduced into 40 private Bills, and a clause regulating the manufacture and sale of ice-cream had been embodied in many others. It was an accepted principle in dealing with private Bills, that when a clause of this sort had been granted to a number of local authorities it was very rarely refused to other local authorities of equal importance who applied for it. However, the drawback was that these local authorities had to go to the expense of promoting Bills in Parliament in order to obtain the extended powers. He would instance to their lordships a private Bill containing 290 clauses which was before the House. What the expenses of that Bill would be he would be afraid to say. However, it was a fact that if a new Public Health Bill of the kind to which he had alluded were passed into law at least from one-third to one-half of the clauses of this lengthy private Bill would be rendered unnecessary. The same remark applied to other Bills. Now what he would suggest to His Majesty's Government was that if a Bill on public health matters were introduced in either House of Parliament by someone who was not a member of the Government, but who was specially qualified to deal with the subject, it should do what it could to assist the measure through Parliament, and that in the course of its passage it should refer it to a joint committee of both Houses consisting of those who had been accustomed to deal with police and sanitary clauses.

Earl OARINGTON replied on behalf of the Government. He said that the proposal made by the noble earl would be a saving to the ratepayers. However, the question raised by him was not entirely free from difficulty. A Bill on the subject had been brought into the House of Commons last year by a private Member. It consisted of 101 clauses referring to a great number of subjects, such as infectious diseases, milk, common lodging-houses, recreation grounds, &c. It was necessary that careful consideration should be given how far such a measure was capable of adoption. He was happy to be able to say that no last word on this subject had been said by the President of the Local Government Board. He did not think that Mr. Burns would wish to bring forward any excuse as to the congestion of business to prevent him from introducing any reform of this sort which would be to the great advantage of the country. The President of the Local Government Board quite realised the desirability of giving greater sanitary powers to local authorities. He had a very warm sympathy with the objects which the Earl of Onslow had in view. At present his right honourable friend was unable to give any pledge on the subject,

although he was giving it careful consideration with a view to action being taken with regard to it. He hoped that answer would not be unsatisfactory to the noble earl.

The Earl of Onslow: The question I asked was whether, if such a measure were brought in by a private Member, His Majesty's Government would give it its sympathy and refer it to a joint committee with a view of getting it through this session.

Earl OARINGTON: I wish I could answer that question, but at present I cannot.

The subject then dropped.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 6TH.

The Sale of Tuberculous Milk.

Mr. H. H. MARKS asked the President of the Local Government Board whether, in view of the statement in the second interim report of the Royal Commission appointed to inquire into the relations of human and animal tuberculosis, that cow's milk containing bovine tubercle bacilli was clearly a cause of tuberculosis, and of fatal tuberculosis, in man, he would consider the necessity of measures more stringent than those at present enforced being taken to prevent the sale or the consumption of such milk.—Mr. JOHN BURNS: I am giving consideration to the report of the Royal Commission and in connexion with it I will bear in mind the point to which the honourable Member refers.

THURSDAY, MARCH 7TH.

Defective Eyesight in Irish School Children.

Mr. JOHN REDMOND asked the Chief Secretary to the Lord Lieutenant of Ireland whether his attention had been called to the promise given by Mr. Bryce on Nov. 18th, 1906, that he would without delay commend to the consideration of the Commissioners of National Education in Ireland the necessity of collecting information on the subject of the alleged increase of defective eyesight of children attending public schools in Ireland; whether any steps had been taken in this matter; and whether the Commissioners proposed to make any arrangements, such as existed in England, for the testing of the sight of these children and for guarding against any further increase of the scourge of defective eyesight.—Mr. BIRRELL answered: My attention has been called to this matter. The Commissioners of National Education inform me that they have issued a number of queries to the teachers relative to the eyesight of children attending national schools. The teachers' statements will be carefully tabulated and considered when received. The Commissioners state that they have no means of providing for the testing of the children's sight. The steps which have been taken in this respect in England have been instituted by local authorities of their own motion.

The Butter Bill.

Answering Mr. W. REDMOND, Sir EDWARD STRACHEY said: I am afraid that no opportunity will be found for the second reading of the Butter Bill before the Easter recess, but it is hoped that the second reading of the Bill may be obtained soon after. The Bill does not affect the amount of moisture permissible in Irish salt brine butter unless it has been blended or re-worked in a factory.

The Dietary of Paupers.

Mr. JOWETT asked the President of the Local Government Board whether he had read the observations contained in the report of Mr. E. A. Baginval, one of the Board's inspectors, on the scale and standard of food in the workhouses, which he thought was too high. In the course of which he stated, on the authority of some alleged scientific discoveries, that the body adapted itself rapidly to any change of diet, and advised that careful attention to that fact should be given when paupers were being fed at the public expense; whether it was the intention of the Board to act on the scientific discoveries mentioned by Mr. Baginval and experiment upon paupers in the matter of food; and having regard to Mr. Baginval's further observation to the effect that cheap food in the shape of stale cheese, bread bits, bacon and liver bits, and bones from the butchers' shops were available for human food in all large towns, whether he would say if these inquiries were made with his sanction.—Mr. JOHN BURNS replied: I have seen the observations in Mr. Baginval's report. The Local Government Board has no intention to experiment upon paupers in the matter of food. No sanction on the part of the Board was given to his making the inquiries referred to in the question, nor was any such sanction necessary. He acted in the matter in the exercise of his own discretion.

MONDAY, MARCH 11TH.

Food Inspection in London.

Mr. ALDEN asked the President of the Local Government Board whether the Public Health (Regulations as to Food) Bill would contain any scheme for creating a uniform system of food and meat inspection throughout the whole of the London area.—Mr. JOHN BURNS replied: The Bill which is now before the House does not itself prescribe schemes. It enables regulations to be made by the Local Government Board for the prevention of danger to public health from the importation, preparation, storage, and distribution of food, and one of its objects is thereby to secure uniformity and efficiency of inspection in the case of particular foods or classes of foods for which control is necessary in the interests of public health whether in London or elsewhere.

The Sanitary Condition of Lewis.

Mr. WEIR asked the Secretary for Scotland whether he was aware that in the last report of the Local Government Board for Scotland it was stated that the present condition of affairs in the Island of Lewis was not to be allowed to continue, and that it was essential that there should be in the district a proper staff consisting of a medical officer of health and at least one sanitary inspector, giving their whole time to their duties.—Mr. SINGLAIR answered: I am well aware of the facts. The matter is under the serious consideration of all the departments concerned, but, as my honourable friend knows, it is not a simple problem, and I am not at present able to make any statement. In answer to a further question by Mr. WEIR, Mr. SINGLAIR said that no portion of the general aid grant for Scotland for the financial year 1907-08 would be specifically set aside to meet the public health requirements of the Island of Lewis, but it would be open to any school board to apply its share of the grant or any portion of it to improving the health condition of its schools.

White Phosphorus in Matches.

In the course of a long written answer to Sir CHARLES DILKE, dealing with the number of persons employed in match factories in this country, Mr. GLADSTONE stated that many of the persons employed in the factories which manufactured white phosphorus matches were not exposed to the phosphorus. He had laid upon the table of the House a report on the recent case of phosphorus poisoning at Messrs. Morelands which also contained some observations upon the general question. He was considering what action to take upon it but he was unable at present to say whether a further report would prove to be necessary.

The Inspection of Boneless Meat.

Mr. FIELD asked the President of the Local Government Board whether he had made any arrangement for the inspection of imported boneless meat; whether he had made any inquiries respecting how it was prepared; whether it was inspected before being frozen; whether he could state how it was disposed of in this country; and whether it was used extensively in the manufacture of pork sausages.—Mr. JOHN BRASS replied (by written answer): I have no authority to make an arrangement of the kind referred to in the first part of the question in the absence of such powers as are proposed to be given by the Public Health (Regulations as to Food) Bill now before the House. I have caused inquiries to be made as to the preparation of boneless meat. It is, of course, liable to whatever inspection is required by the laws of the country from which it comes, and packages of it frequently bear labels stating that inspection has taken place, presumably before freezing. I understand that imported boneless meat is supplied to makers of various meat preparations in this country and that imported boneless pork is employed in the manufacture of pork sausages. The Local Government Board's Inspector of foods ascertained that in 1905 the importation of the kind of boneless pork specially used for sausage making amounted to about 130 tons.

Epidemics in a Workhouse School.

Sir WALTER FOSTER asked the President of the Local Government Board whether he was aware that, owing to continued overcrowding in the workhouse school belonging to the Brentford board of guardians, an outbreak of ophthalmia occurred in November, 1904; that in September, 1905, a second outbreak, affecting over 150 children, occurred; and that during January last an outbreak of diphtheria affecting over 50 children, some of whom died, occurred; and whether he would urge upon the guardians the necessity of boarding out within and beyond the union of children eligible for that method, and of hastening the arrangements for placing others in scattered homes within the union in order to relieve the long-standing overcrowding of the school.—Mr. JOHN BRASS (by means of a written answer) replied: I am aware of the facts as to the outbreaks referred to and that from time to time there has been overcrowding in the school. I am very desirous that measures should be taken to prevent future overcrowding in respect of the children, and I understand that the guardians have had various schemes before them for providing further accommodation for them. They have met with difficulties in the matter, but various arrangements have been made to reduce the pressure, and steps are now being taken to provide certain scattered homes. I shall not lose sight of the subject.

TUESDAY, MARCH 12TH.

A Case of Phosphoric Necrosis.

Mr. ARTHUR HENDERSON asked the Secretary of State for the Home Department whether the special rules for match factories dealt with cases in which a worker was in such a state of health as to incur danger from his work; if so, why, in the recent fatal case, a man, stated to have long been known to have the seeds of necrosis in his system, was exposed to phosphorus poisoning, and at what point the dentist had first referred the case to the certifying surgeon; and whether at any time this man was reported by His Majesty's Inspector of factories as having the seeds of necrosis in his system.—Mr. GLADSTONE answered: Yes, sir. The rules provide for periodical examination by the dentist whose duty it is to suspend the worker whenever he finds danger of necrosis by reason of bad teeth or exposure of the jaw, and, moreover, to report to the certifying surgeon if there be inflammation or necrosis of the jaw or such a state of health as to involve danger of necrosis. As regards the second part of the question, I perhaps conveyed a wrong impression in the reply I gave to Sir Charles Dilke on Feb. 25th. No suspicion of necrosis arose in the case referred to until after the extraction of a tooth on Dec. 19th last, when the necrosis was found and the case was at once referred by the dentist to the certifying surgeon. It was the discovery then made, when taken in connexion with the history of the fracture of the man's leg, which led to the conclusion that phosphorus had begun to affect his system long before.

The Inspection of Imported Meat.

Sir WILLIAM BULL asked the President of the Local Government Board what action, if any, he proposed to take on Consul Finn's report on the Chicago meat scandals.—Dr. MACMURRAY (who replied on behalf of Mr. BULL) said:—My right honourable friend has introduced a Bill which, if it passes into law, will enable the Local Government Board to make regulations with regard to the importation, preparation, storage, and distribution of foods. In adopting this course he has taken into consideration not only this report but also information collected from various sources regarding the wholesomeness of the imported meat which is especially in question.

WEDNESDAY, MARCH 13TH.

The Teaching of Hygiene.

In the course of the debate on the report of the Vote of Account with respect to the Civil Service and Revenue Departments, Dr. V. H. HUTCHINGS advocated the compulsory teaching of hygiene and temperance in all elementary schools. He said that the Committee on Physical Deterioration came to the conclusion that the three causes of degeneration in this country were bad food, bad housing, and alcoholism. It was high time that the Board of Education took steps to remedy this unhappy and unsatisfactory state of things. Two years ago a very large number of medical men signed a petition asking Parliament to make the teaching of hygiene compulsory. He regretted that this had not been done. He urged that it should be made a compulsory subject in the Education Code. The

Education Department should encourage the teaching of hygiene. He also thought that the Board of Education should have a bureau of medical men to help with advice, not only on this subject but on other matters.

Mr. McKENNA (President of the Board of Education) in reply said that if temperance and hygiene, and particularly medical hygiene, were to be compulsorily taught in schools they must have teachers who were competent to give the instruction. At present hygiene was an optional subject. He would give his most earnest attention to the subject. Everything was being done to qualify teachers for teaching it. He could add nothing more to his statement at present.

BOOKS, ETC., RECEIVED.

ALCAN, FÉLIX, Boulevard Saint-Germain, 108, Paris.

Polyclinique Physiothérapique. Effets obtenus par la Bainéation Carbogazeuse (Spécialisation fonctionnelle de Royat) chez les Malades hypertendus et les Malades Insuffisants du Cœur. Par L. Landouzy, Professeur de la Clinique Laennec à la Faculté de Médecine de Paris et Jean Heitz, Ancien Interne des Hôpitaux de Paris, Médecin Consultant à Royat. Price not stated.

YORK, NORTH RIDING LUNATIC ASYLUM, Oulton.—Junior Assistant Medical Officer, unmarried. Salary £150 per annum, rising to £200, with rooms, board, attendance, &c.

Births, Marriages, and Deaths.

BIRTHS.

BEATH.—On March 8th, at Barnard House, Bat's, the wife of David Leslie Beath, M.R.C.S., of a son.

FLETCHER.—On March 8th, at Harley-street, W., the wife of Herbert Morley Fletcher, M.D., of a daughter.

STUART.—On March 8th, at Dun-darach, Camberley, the wife of W. L. Stuart, M.D., B.S. Lond., of a son.

DEATHS.

FARNCOMBE.—On March 6th, at Fairies, Chudleigh, S. Devon, Edgar Leonard Farncombe, M.A., M.B., B.Ch. Oxon., M.R.C.S., L.R.C.P., in his 32nd year, of pneumonia.

FISHER.—On March 10th, at Shere, Guildford, Surrey, Charles Fisher, M.D., M.R.C.S.E., L.R.C.P.L., D.P.H. Camb., aged 39 years.

HILL.—On March 3rd, at Chalford Hill, Stroud, Glos., Frederick A. Hill, M.D., aged 63 years.

KING.—On Feb. 18th, at Ludlow, Shropshire, Ernest Edward King, M.R.C.S. Eng., youngest son of the late Simeon John King, of Saffron Walden, Essex.

MACAULEY.—On March 7th, at 17, Norvern-road, South Kensington, William Robert Macauley, M.R.C.P.I., L.R.C.S., L.M., aged 64.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

BILLINGSGATE.

THE Billingsgate and Leadenhall Markets Committee of the Common Council has presented to the Court of Common Council a recommendation to the effect that it be referred to the former to consider the propriety of applying to Parliament to abolish Billingsgate Market and to utilise for the great public fish market of London a site at Shadwell or elsewhere and to report fully upon the subject. This recommendation was carried in spite of some strenuous opposition and of the moving of an amendment asking for further information as to the need for it. Probably few of the general public take a very active interest in the matter, which at the same time affects very considerably Londoners and all those who derive their fish supply from London looked upon as a distributing centre. The object of the suggested change is to promote a more rapid and easy handling and distribution of the enormous quantities of fish brought to the London market, quantities stated in the Court of Common Council to have been nearly doubled in the course of the last 31 years. The merits of the particular change which ultimately may be made will no doubt be very carefully considered first, but that improvement should be possible, or that change of some kind is required, or, indeed, that it can hardly fail to be beneficial to the community, cannot be doubted by anyone who takes a walk in the immediate vicinity of the present market during business hours and who considers how essential the question of time is when such a perishable article as fish has to be conveyed to the consumer. Perhaps some day in a less-congested market, approached by wider thoroughfares, the language of Shadwell will be typical of the improved circumstances in which it is spoken, and "Billingsgate" as a dialect will be forgotten or become merely a subject of study and speculation for the learned.

A QUESTION OF ETHICS.

To the Editors of THE LANCET.

SIRS,—I notice in your issue of March 9th, p. 701, a letter from a correspondent who, being apparently afraid of his identity being established, signs himself "Esquiver." Being the poor medical officer of health to an urban district referred to I trust you will grant me a few lines to reply. As for my friend the borough medical officer of health, I have no doubt he is well able to look after himself should he deem your correspondent's letter worthy of notice. The facts are as follows. On Thursday evening, Feb. 23th, I was wired to by a firm of solicitors asking me to inspect certain property and appear in court next morning at 11 A.M. to give evidence respecting its condition. I knew nothing further of the affair. I went and inspected the property and found that two of the six houses had considerable repairs done to them, including concrete floors (not asphalt, as your correspondent says) and, in my opinion, they were then (and that was the time being dealt with) not some months before, quite fit for human habitation. I said so in my evidence and I maintain so still. I also deny that at the time in question damp was to be seen trickling down the walls of these two houses, as your correspondent avers. Now, Sirs, whilst acknowledging that the Local Government Board Inspector had every right to express his own opinion some months before when the houses had not been put in repair, and that the county medical officer and local medical officer had a perfect right to express their opinion in the police court at the time I appeared to give evidence, I claim an equal right to my opinion and also to express such opinion, although your correspondent thinks that no opinion should be given contrary to the opinion of the three aforementioned gentlemen. With regard to his attempt to suggest that my conduct in doing so was a breach of ethics it simply shows his ignorance of ethics and is ludicrous.

In conclusion, I would say that the builder, the councillors, and all the persons interested in the houses are entire strangers to me.

I am, Sirs, yours faithfully,

G. H. PEARCE, D.P.H. Cantab.

Darton Hall, nr. Barnsley, March 8th, 1907.

* * * We publish this letter with pleasure.—ED. L.

THE DEATH OF DOWIE.

THE amazing charlatan John Dowie, founder of the "Christian Catholic Church" and of "Zion City," but some time since deposed from his autocracy, has died, and little more need be said about a person whose career, as far as we are aware, contained no incidents worth recording to his credit. Born in 1847, he first became prominent after a chequered and unprosperous early history in 1883, the year of the exhibition at Chicago. During the years that followed he enjoyed extraordinary success, and although he had not been altogether triumphant outside his own country, we feel some satisfaction in believing that he received his first serious check in London. Indeed, there must be an appreciable number of young medical men making their way in the practice of their profession who can remember with a smile of satisfaction somewhat uproarious scenes in which when medical students they questioned the prophet's power

to heal disease at the St. Martin's Town Hall. His abuse of our King no doubt added to the contempt with which Dowie was regarded by Britons, but nearer to his own home his greed and his curious financial methods rather than the absurdity of his quackery or of his religious doctrines led to his downfall, although no doubt his followers were disposed latterly to view with mistrust the fact that at the time of his daughter's death he had summoned a medical man to attend her, a failure to support his own claims to which emphasis was lent when he himself became stricken with paralysis. He was an extraordinary product of an age too highly civilised to deal with impostors of his type as criminals. At an earlier date in the history of mankind he would no doubt have been deterred by fear of the stake or the block, or would have brought upon himself a fate which would have saved his fellow men from much pecuniary loss and bodily suffering.

UNDESIRABLE PUBLICITY.

To the Editors of THE LANCET.

SIRS,—My attention has been drawn to a paragraph in the People of last Sunday (10th inst.) in which my name has been mentioned. I need scarcely add that this has been done entirely without my knowledge and much to my regret.

I am, Sirs, yours faithfully,

Upper Wimpole-street, W., March 12th, 1907. W. ERNST MILES.

THE LAND QUESTION IN THE HIGHLANDS.

DR. Lachlan Grant, who is well known to our readers by his victory and that of the workmen whose medical attendant he was in the Ballachulish quarries dispute, has forwarded to us a report of an address delivered by himself at Oban on the land question. The address was given under the auspices of the Highland Crofters and Cottars' Association, and its object was to bring about the holding of small plots of land by the peasantry. The matter is too purely a political question for our columns, although, of course, it has its medical side, in that if productive land were more easily to be acquired than it is at present the rush to the towns would be stayed and the ideal backbone of a country—namely, a strong healthy peasantry—would again be in process of production. Dr. Grant believes that in the past the tenants of some small holdings have been able to live in moderate comfort on the products of their land, but, on the other hand, it must be remembered that their homes are often insanitary, witness the Blue-book which was issued in 1905 upon the Sanitary Conditions of the Lewis and commented upon in THE LANCET of Sept. 23rd, 1905, p. 904.

THE HISTORY OF MEDICINE.

To the Editors of THE LANCET.

SIRS,—Can you recommend any works dealing with the history of medicine?

I am, Sirs, yours faithfully,

March 5th, 1907.

W. B. H.

* * * Our correspondent's question being somewhat wide it is difficult to give a definite answer. The best short compendium of the history of medicine is a book published some ten years ago and called "A History of Medicine from the Earliest Times," by E. B. Withington. A more lengthy modern work is one in German by Gurlt. Our correspondent might also consult the FitzPatrick Lectures delivered before the Royal College of Physicians of London. The lectures up to the present have been delivered by Dr. J. F. Payne and Dr. Norman Moore and abstracts of the lectures delivered have appeared in THE LANCET of June 27th and July 4th, 1903, Nov. 12th and Nov. 19th, 1904, Nov. 18th and Nov. 25th, 1905, and Nov. 17th and Nov. 24th, 1906. The first set of these lectures has been published by the Clarendon Press as a book and the other lectures will be published in book form in due course. If our correspondent desires to look at any more books on the subject he will find some 40 pages of works in the index catalogue of the library of the Surgeon-General's Office in the United States Army, published at Washington in 1887. The most recent book on the subject which we know of is "Geschichte der Medizin," by Dr. Max Neuburger, in two volumes, Stuttgart, Ferdinand Enke, 1906.—ED. L.

WANTED—A HOME.

To the Editors of THE LANCET.

SIRS,—Can any of your readers help me in the following case? A young lady who was a patient of mine some six months ago with consumption and is now in very good health, though not thoroughly sound, seeks employment. She is a refined and charming woman, well educated, and an excellent needlewoman. If any medical man has a young girl with early consumption under his care who needs a companion with a knowledge of open-air treatment I can conscientiously recommend this lady. She would accept a small salary in return for employment of such kind.

I am, Sirs, yours faithfully,

HERAPATH WOOD,

Medical Superintendent of the Liverpool Open Air Sanatorium, March 6th, 1907.

THE "GLASEPTIC" NEBULISER AND SPRAY.

THE most important feature of both the nebuliser and the spray is that the "atomising" section of the apparatus consists entirely of glass, so that there are no metal fittings to corrode or to oxidise. Moreover, the apparatus is readily cleaned and may, in fact, be kept aseptic.

The "glaseptic" nebuliser is designed for use with solutions having an oil base, but it answers equally well with spirituous, aqueous, or concentrated saline solutions. It may be used for the treatment with spray of both the nasal and respiratory passages. The glaseptic spray gives a very finely divided vapour and for this purpose responds best with aqueous or alcoholic solutions. The apparatus is made in one piece and, like the "nebuliser," can be scientifically cleaned. Messrs. Parke, Davis, and Co. of 111, Queen Victoria-street, London, E.C., supply the "glaseptic" nebulisers and sprays.

Z. Y. X.—We have not the least idea how it has come about that the details of what our correspondent describes as "a remarkable operative cure" have found their way into the lay press. The author must be annoyed at the manner in which uneducated critics are extolling him as a pioneer in surgery and psychology.

Country Practitioner.—The point is left to the discretion of the medical man. Regularly to employ a dispenser as a dentist would be an act of covering, but the performance of a simple extraction in emergencies or under supervision by a dispenser would probably not be regarded by the General Medical Council as an offence.

Necessary.—We cannot guess what a medical man might recommend to our correspondent, whose condition we do not know, nor do we prescribe in these columns. We suggest that "Necessary" should submit his sensible questions to his medical adviser.

C. V. B.—We do not give medical advice to the public. The question is one that can be answered by our correspondent's medical adviser.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

Medical Diary for the ensuing Week.

OPERATIONS.

METROPOLITAN HOSPITALS.

MONDAY (18th).—London (2 P.M.), St. Bartholomew's (1.30 P.M.), St. Thomas's (3.30 P.M.), St. George's (2 P.M.), St. Mary's (2.30 P.M.), Middlesex (1.30 P.M.), Westminster (2 P.M.), Chelsea (2 P.M.), Samaritan (Gynaecological, by Physicians, 2 P.M.), Soho-square (2 P.M.), City Orthopaedic (4 P.M.), Gt. Northern Central (2.30 P.M.), West London (2.30 P.M.), London Throat (9.30 A.M.), Royal Free (2 P.M.), Guy's (1.30 P.M.), Children, Gt. Ormond-street (3 P.M.), St. Mark's (2.30 P.M.).

TUESDAY (19th).—London (2 P.M.), St. Bartholomew's (1.30 P.M.), St. Thomas's (3.30 P.M.), Guy's (1.30 P.M.), Middlesex (1.30 P.M.), Westminster (2 P.M.), West London (2.30 P.M.), University College (2 P.M.), St. George's (1 P.M.), St. Mary's (1 P.M.), St. Mark's (2.30 P.M.), Cancer (2 P.M.), Metropolitan (2.30 P.M.), London Throat (9.30 A.M.), Samaritan (9.30 A.M. and 2.30 P.M.), Throat, Golden-square (9.30 A.M.), Soho-square (2 P.M.), Chelsea (2 P.M.), Central London Throat and Ear (2 P.M.), Children, Gt. Ormond-street (2 P.M., Ophthalmic, 2.15 P.M.), Tottenham (2.30 P.M.).

WEDNESDAY (20th).—St. Bartholomew's (1.30 P.M.), University College (2 P.M.), Royal Free (2 P.M.), Middlesex (1.30 P.M.), Charing Cross (3 P.M.), St. Thomas's (2 P.M.), London (2 P.M.), King's College (2 P.M.), St. George's (Ophthalmic, 1 P.M.), St. Mary's (2 P.M.), National Orthopaedic (10 A.M.), St. Peter's (2 P.M.), Samaritan (9.30 A.M. and 2.30 P.M.), Gt. Ormond-street (9 A.M., Aural, 2 P.M.), Tottenham (2.30 P.M.), St. Peter's (2 P.M.).

SATURDAY (23rd).—Royal Free (9 A.M.), University College (2 P.M.), Middlesex (1.30 P.M.), St. Thomas's (2 P.M.), London (2 P.M.), Charing Cross (2 P.M.), St. George's (1 P.M.), St. Mary's (10 P.M.), Throat, Golden-square (9.30 A.M.), Guy's (1.30 P.M.), Children, Gt. Ormond-street (9.30 A.M.).

At the Royal Eye Hospital (2 P.M.), the Royal London Ophthalmic (10 A.M.), the Royal Westminster Ophthalmic (1.30 P.M.), and the Central London Ophthalmic Hospitals operations are performed daily.

SOCIETIES.

MONDAY (18th).—MEDICAL SOCIETY OF LONDON (11, Chandos-street, Cavendish-square, W.).—8.30 P.M.: Address:—Prof. J. B. Murphy (Chicago).

TUESDAY (19th).—PATHOLOGICAL SOCIETY OF LONDON (Royal Army Medical College, Examination Hall).—5 P.M.: Papers:—Major H. W. Grattan: A Note on Blackwater Fever in Sierra Leone.—Major W. S. Harrison: (1) A Pseudo diphtheria Bacillus from a Case of Middle Ear Disease; (2) Bacillus Typhosus from Peritoneal Abscess One Year after Typhoid.—Lieut.-Colonel W. B. Lelsham: (1) Typhoid Inoculation in the Army; (2) Observations on the Sporo-chlores of Relapsing Fever and Tick Fever (with demonstration).

WEDNESDAY (20th).—ROYAL MICROSCOPICAL SOCIETY (20, Hanover-square, W.).—8 P.M.: Exhibition of Specimens of British Mycetozoa by Mr. A. E. Hilton. Paper:—Mr. J. Murray: Some South African Tardigrada.

ROYAL METEOROLOGICAL SOCIETY (Institute of Civil Engineers, Great George-street, Westminster, S.W.).—7.30 P.M. Lecture:—Major B. F. S. Baden-Powell: The Exploration of the Air (Illustrated by models and lantern slides).

SOCIETY OF ARTS (John-street, Adelphi, W.C.).—8 P.M.: Mr. J. B. O. Kershaw: Smoke Prevention in Factories.

THURSDAY (21st).—NEUROLOGICAL SOCIETY OF THE UNITED KINGDOM (11, Chandos-street, Cavendish-square, W.).—9 P.M.: Clinical Meeting. Patients in attendance at 8 P.M.

FRIDAY (22nd).—CLINICAL SOCIETY OF LONDON (20, Hanover-square, W.).—8 P.M.: Clinical Evening for the Exhibition of Cases followed by Discussion. Patients in attendance from 8 to 9 P.M.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

MONDAY (18th).—ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 P.M. Lecture:—Prof. C. F. Beadles: The Cerebral Arteries (Illustrated by specimens, drawings, and lantern slides).

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chancery-street, W.C.).—4 P.M.: Dr. S. H. Doris: Ointment. (Skin.) 5.15 P.M.: Lecture:—Mr. L. Paton: Retro-bulbar Neuritis.

POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—12 noon: Pathological Demonstration.—Dr. G. O. Low: 2 P.M.: Medical and Surgical Clinics. X Rays. 2.30 P.M.: Operations. Mr. Dunn: Diseases of the Eye. 5 P.M.: Clinical Lecture:—Mr. Paget.

NORTH-HAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—Cliniques:—9.30 A.M.: Surgical Out-patient (Mr. H. Evans). 2.30 P.M.: Medical Out-patient (Dr. Whipple), Throat, Nose, and Ear (Mr. Carson); X Ray (Dr. Pirie).

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 P.M.: Operations. 2.30 P.M.: Sir D. Duckworth: Medicine. 3.15 P.M.: Mr. W. Turner: Surgery. 4 P.M.: Dr. St. Clair Thomson: Diseases of the Throat, Nose, and Ear. Out-patient Demonstrations:—10 A.M.: Surgical and Medical. 12 noon: Ear and Throat. 4 P.M.: Special Lecture:—Dr. St. Clair Thomson: Hoarseness.

TUESDAY (19th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chancery-street, W.C.).—4 P.M.: Dr. C. T. Williams: Ointment. (Medical.) 5.15 P.M.: Lecture:—Dr. P. Stewart: Traumatic Affections of the Spinal Cord.

POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—10 A.M.: Dr. Moullin: Gynaecological Operations. 2 P.M.: Medical and Surgical Clinics. Dr. Ball: Diseases of the Throat, Nose, and Ear. X Rays. 2.30 P.M.: Operations. Dr. Abraham: Diseases of the Skin. 5 P.M.: Clinical Lecture:—Mr. Dunn.

NORTH-HAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—Cliniques:—10.30 A.M.: Medical Out-patient (Dr. Auld). 2.30 P.M.: Gynaecological Out-patient (Dr. Giles), Surgical Out-patient (Mr. Edmunds). Surgical Operations (Mr. Carson).

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 P.M.: Operations. 2.30 P.M.: Dr. R. T. Hewlett: Medicine. 3.15 P.M.: Mr. Carless: Surgery. 4 P.M.: Mr. M. Morris: Diseases of the Skin. Out-patient Demonstrations:—10 A.M.: Surgical and Medical. 12 noon: Skin.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC (Queen-square, Bloomsbury, W.C.).—3.30 P.M.: Clinical Lecture:—Dr. Collier: Muscular Atrophy in the Upper Extremity.

ROYAL INSTITUTION OF GREAT BRITAIN (Albemarle-street, W.).—3 P.M.: Prof. W. Stirling: The Visual Apparatus of Man and Animals.

WEDNESDAY (20th).—ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 P.M. Lecture:—Prof. C. F. Beadles: The Cerebral Arteries (Illustrated by specimens, drawings, and lantern slides).

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chancery-street, W.C.).—4 P.M.: Mr. J. Cunnings: Clinique. (Surgical.) 5.15 P.M.: Lecture:—Mr. J. Poland: The Use and Abuse of Skiagraphy in Fractures and Dislocations.

POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—10 A.M.: Dr. Ball: Diseases of the Throat, Nose, and Ear. Dr. Saunders: Diseases of Children. 2 P.M.: Medical and Surgical Clinics. X Rays. 2.30 P.M.: Operations. 5 P.M.: Dr. Beddard: Practical Medicine.

NORTH-HAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—Cliniques:—2.30 P.M.: Skin (Dr. Meacham), Eye (Mr. Brooks), Medical Out-patient (Dr. Whipple).

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 P.M.: Operations. 2.30 P.M.: Dr. P. Taylor: Medicine. 3.30 P.M.: Mr. Cargill: Ophthalmology. Out-patient Demonstrations:—10 A.M.: Surgical and Medical. 11 A.M.: Eye. 2.30 P.M.: Special Lecture:—Dr. Taylor: Varieties of Spastic Paralysis.

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST (Brompton).—4 P.M.: Lecture:—Dr. O. Wall: The Murmurs of Aortic Incompetence.

CENTRAL LONDON THROAT AND EAR HOSPITAL (Gray's Inn-road, W.C.).—5 P.M.: Demonstration:—Dr. Abrahams: Accessory Sinuses.

THURSDAY (21st).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chancery-street, W.C.).—4 P.M.: Mr. Hutchinson: Clinique. (Surgical.) 5.15 P.M.: Lecture.—Mr. H. J. Curtis: Liver Abscesses, their Etiology, Symptoms, and Treatment.

POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—2 P.M.: Medical and Surgical Clinics. X Rays. 2.30 P.M.: Operations. Mr. Dunn: Diseases of the Eye. 5 P.M.: Lecture.—Mr. Baldwin: Practical Surgery.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—2.30 P.M.: Gynaecological Operations (Dr. Gilles). Cliniques.—Medical Out-patient (Dr. Whitting, Surgical Out-patient (Mr. Carson). 3 P.M.: Medical In-patient (Dr. Chappell). 4.30 P.M.: Demonstration.—Dr. G. B. Price: Clinical Examination of the Crine.

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 P.M.: Operations. 2.30 P.M.: Dr. G. Rankin: Medicine. 3.15 P.M.: Sir W. Bennett: Surgery. 4 P.M.: Dr. H. Cooper: Radiography. Out-patient Demonstrations.—10 A.M.: Surgical and Medical. 12 noon: Ear and Throat.

HOSPITAL FOR SICK CHILDREN (St. Oswald-street, W.O.).—4 P.M.: Lecture.—Dr. Poynton: Rickets, Achondroplasia and Allied Conditions.

ROYAL INSTITUTION OF GREAT BRITAIN (Albemarle-street, W.).—3 P.M.: Dr. C. W. Saleeby: Biology and Progress.

FRIDAY (22nd).—ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 P.M.: Lecture.—Prof. C. F. Beadles: The Cerebral Arteries (illustrated by specimens, drawings, and lantern slides).

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chancery-street, W.C.).—4 P.M.: Dr. H. Tilley: Clinique. (Throat.)

POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—10 A.M.: Dr. Moullin: Gynaecological Operations. 2 P.M.: Medical and Surgical Clinics. Dr. Bell: Diseases of the Throat, Nose, and Ear. X Rays. 2.30 P.M.: Operations. Dr. Abraham: Diseases of the Skin. 5 P.M.: Lecture.—Mr. Bidwell: Operative Treatment of Duodenal Ulcer.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—9.30 A.M.: Cliniques.—Surgical Out-patient (Mr. H. Evans). 2.30 P.M.: Surgical Operations (Mr. Edmunds). Cliniques.—Medical Out-patient (Dr. Anld), Eye (Mr. Brooks). 3 P.M.: Medical In-patient (Dr. Leslie).

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 P.M.: Operations. 2.30 P.M.: Dr. R. Bradford: Medicine. 3.15 P.M.: Mr. McGavin: Surgery. Out-patient Demonstrations.—10 A.M.: Surgical and Medical. 12 noon: Skin. 2.15 P.M.: Special Lecture.—Dr. R. Bradford: Chronic Bright's Disease.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC (Queens-square, Bloomsbury, W.C.).—3.30 P.M.: Clinical Lecture.—Dr. Collier: Torticollis and the Tic.

ROYAL INSTITUTION OF GREAT BRITAIN (Albemarle-street, W.).—9 P.M.: Prof. J. J. Thomson: Rays of Positive Electricity.

SATURDAY (23rd).—POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—10 A.M.: Dr. Bell: Diseases of the Throat, Nose, and Ear. 2 P.M.: Medical and Surgical Clinics. X Rays. 2.30 P.M.: Operations.

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 P.M.: Operations. Out-patient Demonstrations.—10 A.M.: Surgical and Medical. 11 A.M.: Eye.

ROYAL INSTITUTION OF GREAT BRITAIN (Albemarle-street, W.).—3 P.M.: Prof. J. J. Thomson: Röntgen, Cathode, and Positive Rays.

EDITORIAL NOTICES.

It is most important that communications relating to the Editorial business of THE LANCET should be addressed exclusively "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office.

Lectures, original articles, and reports should be written on one side of the paper only, AND WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WRITTEN ON THE BLOCKS TO FACILITATE IDENTIFICATION.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners. Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale and advertising departments of THE LANCET should be addressed "To the Manager."

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

THE INDEX TO THE LANCET.

The Index and Title-page to Vol. II. of 1906, which was completed with the issue of Dec. 29th, were given in THE LANCET of Jan. 5th, 1907.

VOLUMES AND CASES.

VOLUMES for the second half of the year 1906 are now ready. Bound in cloth, gilt lettered, price 16s., carriage extra.

Cases for binding the half year's numbers are also ready. Cloth, gilt lettered, price 2s., by post 2s. 3d.

To be obtained on application to the Manager, accompanied by remittance.

TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newspapers (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and not to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will insure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

THE COLONIAL AND FOREIGN EDITION (printed on thin paper) is published in time to catch the weekly Friday mails to all parts of the world.

The rates of subscriptions, post free, either from THE LANCET Offices or from Agents, are:—

FOR THE UNITED KINGDOM.	TO THE COLONIES AND ABROAD.
One Year £1 12 6	One Year £1 14 8
Six Months 0 15 3	Six Months 0 17 4
Three Months 0 8 2	Three Months 0 8 8

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Offices, 423, Strand, London, W.O.

TO COLONIAL AND FOREIGN SUBSCRIBERS.

SUBSCRIBERS ABROAD ARE PARTICULARLY REQUESTED TO NOTE THE RATES OF SUBSCRIPTIONS GIVEN ABOVE. It has come to the knowledge of the Manager that in some cases higher rates are being charged, on the plea that the heavy weight of THE LANCET necessitates additional postage above the ordinary rate allowed for in the terms of subscriptions. Any demand for increased rates, on this or on any other ground, should be resisted. The Proprietors of THE LANCET have for many years paid, and continue to pay, the whole of the heavy cost of postage on overweight foreign issues; and Agents are authorised to collect, and generally do so collect, from the Proprietors the cost of such extra postage.

The Manager will be pleased to forward copies direct from the Offices to places abroad at the above rates, whatever be the weight of any of the copies so supplied. Address—THE MANAGER, THE LANCET OFFICES, 423, STRAND, LONDON, ENGLAND.

METEOROLOGICAL READINGS.

Subscriptions (which may commence at any time) are payable in advance.

An original and novel feature of "THE LANCET General Advertiser" is a Special Index to Advertisements on pages 2 and 4, which not only affords a ready means of finding any notice but is in itself an additional advertisement. Answers are now received at this Office, by special arrangement, to advertisements appearing in THE LANCET. The Manager cannot hold himself responsible for the return of testimonials, &c., sent to the Office in reply to Advertisements; copies only should be forwarded. Advertisements (to ensure insertion the same week) should be delivered at the Office not later than Wednesday, accompanied by a remittance. Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Office, 423, Strand, London, to whom all letters relating to Advertisements or Subscriptions should be addressed. THE LANCET can be obtained at all Messrs. W. H. Smith and Son's and other Railway Bookstalls throughout the United Kingdom. Advertisements are also received by them and all other Advertising Agents.

The Arris and Gale Lecture

ON

THE PERMANENT DEFENCES OF THE BODY.

Delivered before the Royal College of Surgeons of England
on Feb. 22nd, 1907,

By BERTRAM LOUIS ABRAHAM, M.B.,
B.Sc. LOND., F.R.C.P. LOND.,

ASSISTANT PHYSICIAN, WESTMINSTER HOSPITAL; JOINT-LECTURER IN
MEDICINE, WESTMINSTER HOSPITAL MEDICAL SCHOOL;
EXAMINER TO THE CONJOINT BOARD.

MR. PRESIDENT, FELLOWS OF THE ROYAL COLLEGE OF SURGEONS, LADIES, AND GENTLEMEN,—I beg to thank you for the honour you have done me in appointing me to deliver this Arris and Gale lecture. I feel that the best mode of expressing my gratitude will be to proceed without more ado to the subject which I desire to lay before you.

If we endeavour to penetrate to the actual foundations—the very bedrock—of disease we shall find that our ultimate conception of its causes can be broadly summarised in two words—exhaustion and injury. Amœba may, it is said, be immortal, but it is impossible to conceive of a complex living being which will not eventually break up, die as we call it, as the result of wear and tear. Very few human beings, indeed, come to this end; the battle of life entails wounds and scars, injuries by external and internal noxæ, chemical, physical, and biological, gross and microscopic, any of which, alone or in combination, may contract the vital span. Nor are the two great causes of disease invariably dissociated in their action. There is always the possibility of a *circulus vitiosus*; the injured organ is the sooner exhausted, while noxæ—such as bacteria—find an easy prey in a body brought down by wear and tear. We must at the same time remember that disease processes are not, strictly speaking, new processes. They are simply the normal—or as they are often called physiological—activities of the body perverted by the incidence of the factors which I have just outlined. It follows that a knowledge of physiology is essential to the proper understanding of disease; that the converse is not strictly true, that the findings of experiment are not always directly transferable to clinical medicine, I shall have to point out before the end of this lecture.

One more consideration—derived from biology—must be taken into account in framing our conceptions of disease. Just as there has been a struggle for existence among living beings, so the individual tissues have fought with one another for the mastery. And in both cases the victory has been gained at the cost of greater delicacy, greater vulnerability. The nobler tissues, the elements of the nervous system, of the heart muscle, of great and complex glands like the liver, require a finer pabulum than the plebeian cells—such as those of connective tissue—which surround them. A deterioration in the quality of the pabulum, such as the circulation of a poison—e.g., alcohol or the syphilitic virus—in the blood, will tell first on the former. The parenchymatous elements will weaken, will eventually die, and the connective tissue, which can still thrive on the inferior pabulum, will, like a weed, choke and ultimately replace them. This is, in brief, the story of cirrhosis of the liver and of many of the system-degenerations of the central nervous system.

To-day I propose to discuss what I may call the permanent defences of the organism, defences which are always ready for action and are constantly coming into effect throughout life. They are to be distinguished from those which are only developed in circumstances of special need; these, with which we are not now occupied, may be considered under the general term immunity. Now it is perfectly easy to realise that were it not for some mechanism or series of mechanisms within the body we should be poisoned every day of our lives or would die speedily from some infectious disease. How the former of these contingencies is averted is the problem with which we are at present concerned, and I think that its solution leads itself to explicit demonstration. I shall divide these mechanisms into three chief classes, depending upon their evolution in succession to meet the needs entailed by increasing organic complexity.

No. 4360.

In the first place there is what I have named the physiological reserve or the power which each organ, each tissue, and no doubt each cell, has of calling up its own latent energy in its defence. Secondly, there is the biochemical interrelation of organs, by which one of them can, by chemical means, evoke in another changes which act in its defence. The third, the latest and most complex development, is the nervous mechanism, by which the main organs can call to their aid, not only each other, but the nervous system as well. It acts in an entirely different way than the biochemical apparatus; it is quicker and more easily studied, because, as I shall proceed to show you, there is a definite part of the nervous system set aside for the sole purpose of correlating the organs in this way. Therefore an organ can either (a) defend itself by calling up its physiological reserve; or (b) summon other organs to help it, (1) biochemically, or (2) by the intervention of the nervous system.

I. THE PHYSIOLOGICAL RESERVE.

This is brought into action when any organ, or probably any cell, in the body is subjected to unusual strain. Unwonted and excessive strain imposed upon any organ or tissue or cell of the body calls for its physiological reserve of (biotic) energy. Just as in health a muscle is never completely relaxed, so in health it is never called upon to contract to its utmost. There is a latent power about it, in reserve for ultra-normal stimulation; and similarly in normal circumstances no organ of the body is required to exercise its full functional capacity. There can be no doubt that this reserve enables an injured cell, if not damaged beyond a certain point, to recover; if the lesion goes beyond this point the power to recover is lost. If disease be overcome by this property there will result what the old pathologists were so fond of talking about, the *restitutio ad integrum*, which unfortunately we do not see so often as we could hope. Still, if it does occur it results entirely from this physiological reserve of energy. You know the effects upon an amœba of increasing strength of stimulation. A mild stimulus causes increased pseudopodial movement, a stronger stuns the amœba and causes it to contract into an apparently lifeless ball, a still stronger kills it. If the irritant is insufficient to cause death, enough biotic energy remains to repair the damage and to ensure recovery. We must go back to this simplest of all cases if we are to understand the phenomenon in tissues and organs. In an organ the effect of supernormal strain is to call up the reserve. When the strain is long continued the reserve may be more or less completely mobilised, and the heart muscle, for instance, like the biceps of a blacksmith, will hypertrophy. This may go on for a considerable period and if the mobilisation is sufficient the condition can hardly be called one of disease. A patient with a hypertrophied heart may, if he live an easy and sensible life, go on as a normal individual. Take, for example, that rather rare condition, uncomplicated aortic stenosis. In these cases, under favourable conditions, the hypertrophic power or physiological reserve of the heart is sufficient to cope with all the needs of the organ and of the body. At the same time the heart, though apparently working efficiently, is not actually doing so, because if it be attacked from another direction—if the reserve has been called out and mobilised, and a fresh enemy appears upon the flank—the army is apt to be thrown into disarray. Again, a patient with mitral stenosis may go on well for several years, living a quiet and apparently normal life, but if he contracts pneumonia the damage to the heart muscle becomes obvious and the machine is thrown out of gear. To change the simile, a patient with compensated valvular disease of the heart is like a man living on his capital. He may not be aware of this until there is a drain upon his bank from some other cause, when he becomes suddenly and acutely conscious that his balance there has sunk to an embarrassing level. This is equally true of other organs, though it may not be quite so easy to demonstrate. A patient may go on with damaged kidneys for an indefinite number of years. Then some acute infection supervenes and the injured organs are unable to withstand the strain. General metabolism has perhaps also suffered, and the patient succumbs or, at any rate, has a severe illness. Thus an intercurrent malady may carry off a patient who has attained an apparent equilibrium. One sees, for instance, persons who have had diabetes for many years die suddenly from coma following an ordinary attack of influenza.

This leads me to digress for a moment in order to mention more particularly one of the chief, though least recognised.

causes of the breaking strain. This is, if I may borrow a term from chemistry, supersaturation. You know that you can dissolve an excess of a salt, such as ammonium chloride or zinc sulphate, in water, more than is normally held in solution. As long as this is not disturbed nothing will happen; but if you drop in a crystal or merely agitate the fluid the whole mass will suddenly crystallise. Now consider the case of a patient who has been addicted to long-continued excess in alcohol, who has soaked his nervous system in this fluid for a number of years. He may inform you that he has taken "a reasonable amount" to drink but that he has never been drunk; nor has he ever had symptoms which have been referable to alcoholism. One day he breaks his leg and the next morning he has delirium tremens, or the same complication develops in the course of an attack of pneumonia. Here you have an example of an organ, the nervous system, which through some physiological power has been able to resist, without appearing any the worse, the action of a poison administered in frequent, smallish doses over a considerable period of time. A certain amount of tolerance has been established, and I think that the question of toleration is largely bound up with, and is at all events a part of, the function of physiological reserve. But a man whose nervous system is saturated with alcohol may be suddenly attacked by the symptoms of alcoholism as the immediate result of a fresh stimulus, mechanical or chemical. So may the diabetic develop coma as the consequence of fatigue or influenza, or the nephritic female uræmia when pregnant. I will go further and venture to suggest a similar explanation in the case of chorea. We know that this is a disease which is almost invariably associated with the rheumatic poison. Whatever may be the actual cause of rheumatism, there can be no doubt that the condition of the patient is one of intoxication: he is suffering, in fact, from the continued effects of a virus. Moreover, after excluding imaginary or long distant alarms, a certain number of attacks of chorea are immediately preceded by an actual fright. This seems to me a parallel case. The patient, coming very often of a neurotic stock, was already supersaturated with the rheumatic toxin and the psychical disturbance resulting from the fright was sufficient to bring about crystallisation—i.e., to determine the symptoms of chorea.

To return to the question of the physiological reserve. If the strain is continued long enough, even in the absence of an intercurrent disorder, the energy of the organ may become exhausted and the reserve be used up; the organ or tissue then suffers what may be described in one word as degeneration. In the heart, the example which we have already chosen, the muscle ceases to hypertrophy and the organ dilates. It dilates because there is a struggle for existence between its different tissues; when the muscle energy is exhausted the connective tissue asserts itself and fibroid or fatty change results. Fatty degeneration is in part a reversion to a type of connective tissue and in part the result of other causes connected with metabolism, while fibroid tissue is the typical plebeian tissue which I have already described as constantly lying in wait for any impairment of the more highly organised and vulnerable structures which it interpenetrates.

This sequence of changes is not less marked in the central nervous system. Of course, this does not hypertrophy in the same way as the heart muscle and it is only during the last few years that we have acquired sufficient technical knowledge to enable us to study the actual changes in its finer elements. We know now that neuron complexity increases with education up to the age of 40 years at any rate, and that in some cases far beyond that age the neurons may show greater complexity with progressive development of the mental faculties. Here, in fact, there is definite histological evidence of an adaptation to increasing demands, of, in other words, the utilisation of a physiological reserve. On the other hand, the nervous system may give way if the calls upon it are long-continued and excessive, and especially if it has already been damaged by poisons, such as lead, alcohol, or especially the virus of syphilis.

From this point of view the history of an attack of general paralysis is most interesting. You cannot fail to have noticed that even in hospital practice the sufferers from tabes and general paralysis are as a rule more talented and intelligent than the general run of patients. It is even more striking in private practice to observe the sudden breakdown from general paralysis of intellectually gifted people.

A patient who has suffered from some infection, chiefly, of course, syphilis, with subsequent hard mental work, and particularly, it seems, one who has been subjected to financial worry, is the most likely subject for this disease. This is once more a question of the exhaustion of the physiological reserve. And here again, as the neurons, the most highly organised cells we know, yield to the strain and decay, the neuroglia, the connective tissue which supports them, assumes the mastery, and the fibrous elements supplant the parenchymatous.

Sometimes it appears that an organ enters upon life, so to speak, with an insufficient physiological reserve. Such an organ is imperfectly equipped, compared with the rest of the body, to resist wear and tear. Hence it is that one particular organ or tissue in any person may exhibit a conspicuous vulnerability, may in fact die before its time within the body. If this organ is of vital importance its owner will die too; the heart and the kidney afford good examples. If the death of the organ does not entail that of the individual more or less maiming must follow. This may be seen in Friedreich's disease, where certain tracts of the spinal cord die before their time, crippling and deformity being the result.

The physiological reserve may play a part in yet one other important pathological process, that of repair. We have already seen that it is the sole means by which this can be effected in the case of a unicellular organism. With increasing complexity of structure division of labour is found among the various constituent cells of a tissue. Thus the repair of an injured tissue is mainly brought about by cells other than those damaged by the noxa. It may well be that in these cells is stored the reserve of biotic energy. In a sense less fanciful than was intended by Grawitz, the inventor of the term, they might be called "slumber cells."

II. THE BIOCHEMICAL APPARATUS.

Now let us consider the means by which one tissue may call upon another for help. The first of these is the biochemical. A good deal has been said during recent years upon the subject of internal secretion, as if it were a special function limited to certain organs. But if you think over the matter it will be perfectly obvious that every cell in the body has an internal secretion, that it takes something away from, and gives back something else to, the common stock. Each cell, therefore, must exert some influence over every other cell in the body, and while in some cases this may be no greater than that of a stone cast into the ocean, in others it is most important, wide-reaching, and vital. Some of these secretions are, in fact, essential to life, though their very existence might never have been guessed at had it not been for the effects of disease or removal of the particular organs in which they are formed. We know, for instance, that the essential product of the suprarenals is a body of comparatively low molecular weight, which is not destroyed by boiling, which can be filtered, which can be sterilised, and which has a distinct action upon all muscular tissue innervated by the sympathetic system, especially the smooth muscle in the walls of the blood-vessels.

The thyroid is another example. Although we are still doubtful as to its exact functions we know that this organ is essential to life. In all probability its use is different in younger and older animals. In the latter administration of thyroid extract is followed by increased chemical change in the tissues and augmented nitrogenous metabolism, while in the former the effects produced seem to be more in the direction of increased growth of the tissues in general and more particularly of the connective tissues, including the bones. In the one case katabolism, in the other anabolism, is the more favoured.

Among other secretions which have been shown to have a definite and effective defensive action is so simple a chemical substance as carbonic acid. It has long been established that an increase of CO_2 tension in the blood, above a certain point, causes violent respiratory movements, quite independently of the physical condition of the lungs. If you perform Head's experiment of positive ventilation with hydrogen, which is an indifferent gas, so that while the lungs are kept expanded the blood is not being aerated, you can differentiate between the mechanical effects of inflating the lungs and the consequences of an altered chemical condition of the blood. In this experiment an expiratory rhythm results, but the inflation which produces it, being with hydrogen instead of oxygen, is useless to the animal. The hydrogen, without being an actual poison, is, vitally speaking, useless, and

after a brief interval violent curves, inspiratory as well as expiratory, are seen. These have recently been shown to be due not to the want of oxygen but to the presence of carbonic acid; in other words, the CO_2 produced in the tissues is the defensive agent which calls up violent respiratory attempts to obtain more oxygen for the carrying on of vital processes. This is the simplest example of a chemical messenger, or, as we now call it, hormone, which one tissue can send to another.

Some of these secretions exert a definite stimulant action upon various organs. I have mentioned the suprarenal with its special motor or constrictor influence upon the smooth muscle in the arterioles. One—namely, the digestive mechanism—will serve as an appropriate example, if I give an outline of some of its phenomena. The whole of digestion is a continuous chain of these biochemical responses, which have been called by some reflexes; to employ this term, however, is to attempt to undo all the work which has been done with regard to the differentiation between biochemical and nervous mechanisms. The most conspicuous example, and the only one which I shall give you now, is that of the process of digestion in the upper part of the small intestine. At intervals during gastric digestion a small amount of acid chyme is ejected through the pyloric opening. This acts upon a substance formed in the wall of the small intestine, known as prosecretin, and converts it into secretin. Secretin, which is not a ferment but a true hormone, is then absorbed by the blood and gets to the pancreas. It has been shown experimentally that, when administered to the pancreas, secretin causes a free flow of pancreatic juice, which contains a large amount of trypsinogen. So that prosecretin is converted by chyme into secretin, and secretin evokes trypsinogen. Trypsinogen, when it reaches the intestine, produces the flow of a ferment known as enterokinase. It is not at present certain that trypsinogen is the only factor which causes the outpouring of enterokinase. It may be that mechanical stimulation of the intestine has something to do with it, but all the most recent evidence is in favour of the view that it is trypsinogen, and trypsinogen alone, which stimulates the secretion of enterokinase. Enterokinase now reacts on trypsinogen and converts it into trypsin, which, as you know, in an alkaline medium, digests proteins. But there is something else in addition, because with the trypsinogen, some alkali is also passed out into the small bowel. When this alkali is in sufficient quantity to be in excess of the acid of the chyme, and when in consequence the contents of the duodenum become alkaline, they cause the pyloric sphincter to relax and open. This permits more chyme to come through and the acid which it contains starts the whole mechanism over again, which goes on until the stomach is empty. You will see, therefore, that the pancreatic juice, when evoked by secretin, does two things. It has in it the first place the trypsinogen, which stimulates the presence of enterokinase, which converts trypsinogen into trypsin, and so digests proteins, and secondly, carbonate of soda, which neutralises the acid of the chyme until a point is reached when alkali is in excess, when the pyloric sphincter is opened and more chyme is poured out. Here, then, is a beautiful example of the interrelation of chemical processes as seen in a physiological act, and the more we know of the nature of digestion the more does it appear to be built up of phenomena of this description; so that in the practical consideration of diseases of the digestive organs we have to begin with this kind of study. And it must be remembered that in normal circumstances all these activities are entirely latent. Prosecretin appears to have no action whatever upon the pancreas. If you inject it into the pancreas no secretion of pancreatic juice will result. Trypsinogen possesses almost no proteolytic power; it is not rendered effective in this respect until modified by enterokinase. It is only in these special circumstances, and by the aid of such biochemical responses, that these secretions perform their function, and the whole mechanism must be in full working order for the process of digestion to go on properly.

In other cases, which have been much discussed lately, so that I may summarise them very briefly, the internal secretions may stimulate actual growth. I may here refer to the very striking experiments of Shattock and Seligmann on the relation of the development of masculine characters to the growth of the testicles. By comparing the results of castration and double vasotomy in sheep and fowls they found that the appearance of male-type characters—horns,

spurs, &c.—was prevented by the former but not by the latter, the operations being, of course, performed upon the animals soon after birth. Maleness hence appears to be due to the presence of testicles and not to the procreative capacity of the animals. Moreover, if testicular tissue be grafted in the abdomen, the testicles having been removed, the animal still develops male characters. It is thus evident that the impulse to this species of growth is excited by chemical and not by nervous stimuli.

This has also been worked out particularly in connexion with the mammary gland. Of course, it has long been well known that if the spinal cord of an animal was divided during pregnancy, after parturition the mammary gland started secreting milk as usual, although no nervous connexion existed between it and the uterus. This has been recorded in many cases in the human subject; I remember one which occurred at Charing Cross Hospital a few years ago. Goltz has also demonstrated the same thing most conclusively upon a bitch from which he had removed the whole of the lower part of the spinal cord, so that there can be no doubt that it is a biochemical action which evokes the mammary secretion. The next step was the research of Marshall and Jolly upon the corpora lutea. They found that the ovary formed an internal secretion which was responsible for the function of menstruation, and that when the ovaries were removed menstruation could not occur. Moreover, the corpus luteum contained an internal secretion, which had to do with the fixation and development of the ovum in the early days of pregnancy. That is to say, that if the corpus luteum were removed in an animal soon after impregnation the ovum did not become fixed and did not develop, whereas if it were removed after half the period of gestation had passed development was not interfered with in any way.

This work has been rounded off by a long series of experiments by Starling, having for their object the endeavour to find a means of stimulating the secretion of the mammary gland in unimpregnated animals. He found that he could make an extract from the bodies of foetal rabbits which, when injected into virgin rabbits, produced development of the mammary glands. This extract could be boiled and passed through a Berkefeld filter without losing its properties. It is a hormone, a true chemical product, comparable with suprarenal extract. If injected into a rabbit which had borne young but was not pregnant, it caused the mammary gland to develop and to a certain extent to grow. He came to the conclusion that the foetus in utero pours forth through the placenta an internal secretion into the mother, stimulating mammary growth, and that if during the first half of pregnancy the ovum be removed all that results is atrophy of the glands, which at this time have developed to a certain extent but consist mainly of ducts. Removal of the foetus, however, during the second half of pregnancy acts as a stimulus to the breaking down of cells which by this time have been formed in the mammary gland. Their breaking down under this inhibitory stimulus leads to the secretion of milk. This corresponds with what is known in actual obstetric practice—namely, that the expulsion of the ovum before a certain date results in the mammary gland returning to its former condition, whereas if it occurs afterwards the inhibitory stimulus of the removal of the internal secretion causes the production of milk by katabolic changes in the gland. We here have a most typical example of response to a biochemical messenger—the hormone.

Now and then we seem to discern abortive attempts at the development of these chemical activities. We know that in exophthalmic goitre the thymus is hypertrophied. We know that in acromegaly the thyroid is apt to enlarge. We may regard these as efforts to come to the rescue when damaged organs are sending broadcast appeals in the form of chemical stimuli, to which the various glands try to respond, though in these cases unsuccessfully.

In addition to such efforts to meet special needs there are many other chemical processes of a defensive nature daily at work in the body; these have been carefully studied by Hertel. It will perhaps be as well to outline some of the principal examples.

Poisons are constantly generated in the course of digestion; acetic and lactic acids, indol and phenol, albumoses and peptones, are always being formed in quite large quantity in the intestines. Other poisons, again, are developed in the course of metabolism. Ammonia, which is a virulent organic poison, is always found in considerable amount in the portal vein after a meal, but is normally screened from the general

circulation by chemical changes in the liver. Its presence in excess in the blood or urine is usually the harbinger of evil. Then, again, carbamic and oxybutyric acids may be formed in a somewhat similar manner. Many internal secretions, such as, for instance, that of the suprarenal, if administered in quantity, are poisons, and such an internal secretion which is continually poured into the blood must, unless neutralised in some way, become poisonous. There must hence be a certain number of detoxicating influences at work in the body which prevent these poisons from acting. Such influences are grouped by Hertter under three different headings: (a) processes of oxidation and reduction; (b) processes of hydration and dehydration; and (c) processes of synthesis.

(a) Oxidation gets rid of poisons such as alcohol and acetic acid. We know also that indol, which is produced in considerable amount in the intestines from albumoses and peptones, must be changed in some similar manner. The oxidation which occurs in the tissues usually demands the presence of iron, the alternation between ferrous and ferric salts being associated with the oxidation of bodies which require it. It may be that in other cases, as, for instance, butyric acid fermentation, nascent hydrogen is evolved; this liberates the atoms of nascent oxygen from the molecules and so causes the formation of an acid product. Oxidation cannot go on in the body except in an alkaline medium so that the presence of oxidation depends upon that of bicarbonate of soda, which is the chief alkaline constituent of the blood, and acts no doubt by virtue of its hydroxyl ions. With regard to reduction, you will remember that the injection of methylene blue into the body, as devised by Ehrlich, causes certain organs to become blue while others remain of their normal colour. These latter are those in which reduction is going on, as methylene blue is decolourised when reduced.

(b) Respecting hydration and dehydration, I need only mention the albumoses and peptones. We know that these bodies are formed from native proteids by hydration; moreover, as they are reconverted into native or tissue proteids somewhere in the body, a process of dehydration is also implied.

(c) Many intracorporeal syntheses are well known; I may refer, as examples, to those of hæmoglobin, of fat from carbohydrates, of hippuric acid from benzoic acid and glyccoll. But there are others, a little more recondite perhaps, which are of especial value from the defensive standpoint. An important example is the protection from acid intoxication by means of syntheses. Acid intoxication is a very prominent terminal feature of such a disease as diabetes. The presence of an excess of acid in the blood is a matter of almost inevitably fatal import. There are, however, certain bodies which are ready and able to combine with and to neutralise the acid; the chief of these is ammonia. Ammonia compounds and carbamic acid are built up into urea, which is not a toxin, and similarly when there is a possibility of acid intoxication ammonia tends to neutralise the acid, and ammonia salts are consequently found to excess in the urine. If, therefore, in the course of a case of diabetes, late in which disease the diurnal excretion of urea is usually increased, there is a drop in the amount excreted and a corresponding rise in the ammonia salts, this is of evil omen, and calls for immediate attention, as it is probably a warning of acid intoxication and therefore of diabetic coma. Other salts may to some extent take the place of ammonia, and of these sodium salts and in particular sodium carbonate are the most important in protecting against this intoxication. Thus among the numerous and varied actions of the liver none is more important than its detoxicating power by which it screens the body from the ill-effects of many of the products of digestion and metabolism.¹

III. THE NERVOUS MECHANISM.

The third permanent line of defence is the nervous system; with regard to this I propose only to say a few words now, as its functions are so much more familiarly known. It was at one time more exclusively studied from this point of view than any other part of the body, in fact, all associated action was believed to be either "sympathetic" or "reflex" through the nervous system. Just at

present it is, however, rather under a cloud owing to the great strides which have recently been made in our knowledge of the chemical factors in the correlation of organs. This is, perhaps, a little unjust, for there can be no doubt but that the nervous system plays a most important part in calling one organ to the support of another. Of this no more valuable example need be quoted than pain, which is almost always a safe guide to the presence of something abnormal and requiring our attention. Pain should therefore not be regarded merely as a thing to be done away with by means of analgesics, but as one of the most important symptoms of disturbance in the organic equilibrium. Thus, were it not for the immobility caused by the pain of dislocation or fracture much more damage would be done by the injury. John Hilton's great work, "Rest and Pain," which is, I fear, but too seldom read nowadays, abounds with examples of the beneficent work of the latter.

In addition to this general mechanism there is a special part of the nervous system, set aside for reflex action and for responding to the cells of damaged organs. This is the autonomic nervous system, which is an efferent system dependent upon the sympathetic ganglia, and their branches. It has to do mainly with vascular and glandular reflexes and is known to us chiefly through the admirable researches of Langley; it is one of the most important agencies in the maintenance of blood pressure and in the regulation of secretion. I would at present merely point out that, as in the course of evolution we meet first with the physiological response, secondly with the biochemical response, and thirdly with reflex action, so the physiological response is ever ready to act but is lowly organised, the biochemical is more highly organised, and the nervous system the most specialised of all. Physiological reserve takes days, or weeks, or months to be fully established, the biochemical response takes minutes, while a reflex act occupies but the fraction of a second. The last named may be compared to the navy, which is, or should be, always ready for action; the second to the army, which should be capable of rapid mobilisation; while the physiological reserve is like the militia, oldest in origin and requiring most time to become efficient. Such has been the evolution of the successive lines of defence to meet the needs of the increasing complexity of the organism. And of all of them it must be borne in mind that they may interact; thus a chemical change may cause a nervous response. Excess of CO₂ in the blood acting upon the respiratory nerve-centres in the medulla will produce respiratory movements.

And in the most highly specialised examples of all, where the activity of an organ is of truly vital importance, you will find not only a very elaborate mechanism but in many cases a double mechanism. In the case of respiration, as we have just seen, there is a nervous mechanism acting through the vagi as afferent nerves, and at the back of this, and independent of it in origin, there is a chemical one, controlled by the venosity of the blood in the medulla. In that of the heart we know that the rhythm is myogenic, depending upon the cardiac muscle alone, but that there is also an escapement, a further control by means of the nervous system, so that in these really essential acts of the body there is help from two sets of defensive apparatus.

Nor may we imagine that we know all about these mechanisms. Substantiate them as we may by laboratory experiment, we cannot but feel that in many cases within the living body there may be a "short circuit," a simpler solution of vital problems than can be attained under artificial conditions. And, moreover, we have some evidence that actions may go on in opposite directions in test-tubes and in the body. Diphtheria antitoxin is an excellent medium on which to cultivate diphtheria bacilli, but when injected into the body it not only neutralises their products but seems also to interfere with their growth. To argue from extracorporeal to intracorporeal processes is sometimes little more than absurd. Take, for instance, the coagulation of the blood. Outside the body this is a normal process, having for its object the closure of wounds; inside the vessels it is abnormal and fraught with grave danger. It is to the advantage of the body to favour the one and to hinder the other; so we find intravascular clotting difficult to produce but extravascular difficult to hinder. What are the causes underlying this reversal, so complete and so important? No blind and wholesale application of the facts of physiology to the needs of clinical medicine is here possible. The more extended study of the properties of biotic energy may perhaps reveal in the midst of apparent complexity the bases of organic economy.

¹ Under this heading might reasonably be considered the normal bactericidal action of certain cells and juices. But this part of the subject is more conveniently, if not more logically, to be treated in connexion with the question of immunity.

ABSTRACT OF

The Goulstonian Lectures

OR

CERTAIN ACUTE INFECTIVE OR TOXIC
CONDITIONS OF THE NERVOUS
SYSTEM.

Delivered before the Royal College of Physicians of London

By E. FARQUHAR BUZZARD, M.D. OXON.,
F.R.C.P. LOND.,

ASSISTANT PHYSICIAN TO THE NATIONAL HOSPITAL FOR THE PARALYSED
AND EPILEPTIC, QUEEN'S SQUARE, TO THE ROYAL FREE HOSPITAL,
AND TO THE BELGRAVE HOSPITAL FOR CHILDREN.

LECTURE II.¹

Delivered on March 7th.

MR. PRESIDENT AND GENTLEMEN,—Having in my first lecture referred to the general principles of acute infective or toxic processes in the nervous system, I propose to turn my attention at once to the consideration of the four diseases—acute poliomyelitis, acute ascending myelitis, Landry's paralysis, and acute toxic polyneuritis—and to the discussion of the various interesting questions with which their origin and nature are associated.

ACUTE POLIOMYELITIS.

Not only on account of its comparatively great frequency, of its lamentable and cruel results, but also because its investigation raises many important questions, acute poliomyelitis undoubtedly claims our first attention.

The name.—The two names by which this disease is commonly known are "acute anterior poliomyelitis" and "infantile spinal paralysis." To the first, two objections may be made on the grounds of its length and of its accuracy. The omission of the word "anterior" is a remedial measure suggested by Wickman which is certainly successful in removing the former objection, and, with regard to the latter, has obvious advantages in that it renders the title, as we shall see later, more nearly descriptive of the limits of the disease. The term "infantile spinal paralysis" has little to recommend it, because at the present time most authorities will allow that the disease is common, although in varying degrees, to at any rate the first four decades of life. If we remove the word "infantile" from the name "infantile spinal paralysis" we are left with a far too general term to be of any use. For these reasons I prefer the title "acute poliomyelitis" and do not make any distinction between an infantile and adult form.

MORBID ANATOMY.

Historical.—In order that we may, during the description of anatomical lesions, bear in our minds the various views which have been offered for their explanation I will narrate shortly the pathological history of the disease.

While studying the details of morbid anatomy we shall have to bear in mind several different theories offered for their explanation. 1. A primary degeneration of the ganglion cells of the anterior horns with secondary interstitial fibrosis. 2. An inflammation of the interstitial tissues of the spinal cord due to blood-borne infection with secondary or coincident injury to the ganglion cells. 3. A similar condition, but one which originates and spreads in the lymphatic system—a lymph-borne infection. 4. A primary thrombotic or embolic process in the distribution of the central artery.

Anatomical.—As a basis for the study of the morbid anatomy I will take the case of a man who died from the disease within four days of the first symptoms of illness and within 36 hours of the onset of paralysis. Portions of the central nervous system of this case were kindly sent me by Dr. C. R. Elgood. An athletic man, aged 28 years, with no important preceding illness except a doubtful history of syphilis some years previously complained for two days of pain in the back and limbs and developed a slight pyrexia. On the third day he was confined to bed with a temperature of 101° F. and a furred tongue. The following morning he

was paralysed in the legs and during the day the paralysis involved the trunk and respiratory muscles and death from respiratory failure occurred at midnight. There had been no mental impairment, no loss of cutaneous sensibility, and no disorder of the sphincters. The portions of the nervous system which I had the opportunity of examining were the lower dorsal and upper lumbar segments of the spinal cord together with the medulla oblongata and pons Varolii.

The spinal cord.—All the spinal segments presented similar microscopical features and the description of a section from the twelfth dorsal will suffice for our purpose. Even with the naked eye a section stained with logwood presents a striking difference from the normal. The grey matter stands out from the surrounding white columns unusually well owing to dense accumulation of nuclear elements within it. Under a low power this appearance is accentuated and, in addition, one is struck by the fact that the anterior spinal artery and its branches and a large number of the chief radial vessels are rendered prominent by the intense cellular infiltration of their walls. This condition obtains with regard to the vessels both in the antero-lateral and posterior columns and is often present in the vessels entering with the posterior roots. A more detailed examination shows that most vessels, whether in the white or grey matter, are distended with blood which presents no evidence of ante-mortem coagulation, and that capillary hemorrhages or red cell extravasations are scattered about. In the grey matter it is noticeable that although the nuclear elements are everywhere in excess of the normal they tend here and there to be gathered together in dense foci which may or may not have any obvious association with vessels. These foci are to be seen in the posterior as well as the anterior horns and are often well marked in the neighbourhood of Clarke's column. Even when carefully looked for with higher powers it is difficult to find more than a very few of the anterior horn cells and the majority of these are much changed; they are usually swollen, rounded, and devoid of protoplasmic granules, while their nuclei are often enlarged and excentric. The cells of Clarke's column are similarly affected, although not so completely submerged in surrounding cellular exudation. On the other hand, the white matter is practically free from accumulations of nucleated cells, although the cellular infiltration of the vessel walls is marked, and the neuroglial cells are possibly in some excess. In contradistinction to the grey matter where it is nearly impossible to distinguish the constituent axis cylinders and ganglion cells, in the white matter one is able to detect the usual appearance of axis cylinders and myelin sheaths cut in transverse section, although both axons and sheaths are sometimes swollen, especially in the antero-lateral columns. The soft meninges are also the seat of cellular infiltration, generally confined to the anterior median fissure and the antero-lateral surface but occasionally on the posterior aspects of the cord as well. The cells lie in the spaces of the connective tissue network, which are consequently enlarged and are more numerous in the neighbourhood of vessels.

Medulla and pons.—The changes seen in the pons and medulla are less intense, similar in character, though different in distribution to those of the spinal cord. General hyperæmia with cellular infiltration of the vessel walls is general throughout these regions. Cellular foci in the tissues are scattered irregularly, chiefly in the central formative reticularis but sometimes in the neighbourhood of the nuclei in the floor of the fourth ventricle. Definite ganglion cell changes are confined to those cells which are in the immediate proximity to the cellular foci in the tissues and consist of chromatolysis with or without excentration of nuclei.

So far I have only referred in general terms to the cellular infiltration of the grey substance, of the vessel walls, and of the soft meninges, each of which must be considered separately in greater detail and in the light of their appearances under high powers and different methods of staining. This would have been very incomplete in the particular case I have been describing, owing to the method of fixing the material, but I have been fortunate enough to supplement this by the examination of two other cases, both of five days' duration, from which sections were prepared by Dr. Gordon M. Holmes with the Heldenheim and the Unna-Pappenheim methods in the laboratory of the National Hospital. To the generosity of Dr. Donald W. C. Hood and of Dr. F. E. Batten I am deeply indebted for permission to refer to these sections. In both these cases

¹ Lecture I. was published in THE LANCET of March 16th, 1907, p. 785.

the general appearances I have already described were present in greater or less degree throughout the spinal cord and extended with fading intensity as high up as the optic thalamus.

Cellular infiltration of vessel walls.—This may well be taken first as it is the most widespread change in cases of acute poliomyelitis. In almost all fatal cases it has been found throughout the cord and brain stem and in many it has been traced as far as the cerebral cortex in the one direction and the conus terminalis in the other. The vessels of the grey and white matter are affected alike, veins, capillaries, and arteries all sharing in the process. On the whole the veins and capillaries show, proportionately to their size, a more intense infiltration than the arteries. The cells are seen within the adventitial sheath and often crowded between the media and adventitia in such a way as to bring into prominence a space to which I referred in my first lecture as the lymphatic channel described by Virchow, Robin, and others. The cells constituting this infiltration of the adventitia may be divided into several classes.

1. Cells which have all the morphological characteristics of the lymphocytes of the blood—single round or nearly round nuclei which stain deeply with most dyes, with a narrow rim of protoplasm which is often invisible in logwood sections but which can be generally distinguished by the Heldenheim and Unna-Pappenheim methods. With the latter staining this protoplasm stains a distinct and nearly homogeneous pink. The cells of this class form the large majority of all those contained within the vessel sheath, probably representing a percentage of 80.

2. Cells which are similar to the last class except in the fact that they have more protoplasm. They include all the intermediate forms between the lymphocytoid cells and somewhat larger cells which strongly resemble the plasma cells described by Unna, Marschalko, Vogt, Mott, and other observers in various conditions. These plasma cells are generally oval or oblong in shape, with a rounded nucleus lying either centrally but more frequently at one end. The protoplasm with the Unna-Pappenheim method is a rather bright pink and contains very fine granules. The nucleus resembles that of the lymphocytes except in respect to the chromatin granules which are sometimes more dispersed towards the nuclear membrane. These intermediate cells and plasma cells are found in a proportion of about 10 per cent.

3. In the remaining 10 per cent. are included several different types, each of which is so scantily represented that it requires little attention. There are a few larger mononuclear elements, a few large cells of about the same size with horseshoe-shaped nuclei, a few polymorphonuclear leucocytes, and a few cells with oval clear nuclei and very indistinct protoplasm, probably endothelial in origin.

All the cells I have now referred to are definitely within the meshes or lymph spaces of the adventitial sheath and are quite separate from the surrounding nervous substance; there is, in fact, not the slightest ground for believing that any of them are derived from the neuroglial elements. The infiltration of the vessel walls has been mentioned under the name of perivascular round cell infiltration by all observers who have examined cases of poliomyelitis in the acute stages but most of the earlier investigators have regarded them as emigrating leucocytes. At the present time there is much disagreement with regard to the origin of these lymphocytic and plasma cells and the various views are somewhat as follows.

The origin of these cells is not yet fully understood and I will content myself with merely summarising what is definitely ascertained. In many infective processes of the central nervous system the most marked inflammatory reaction is the perivascular cellular infiltration. In the acute stage of poliomyelitis this infiltration is conspicuous and consists mainly of cells which resemble lymphocytes and of cells which appear to be developing from the latter. The evidence is in favour of their being derived from cells already present in the walls of the vessels and against the view that they have migrated directly from the blood stream. A few polymorphonuclear elements are to be seen but there is no evidence of a free exudation of these cells.

Cellular infiltration of the soft meninges.—This subject is best considered next because the cells which are found here are practically identical with those found in the vessel walls. As I have already mentioned, the infiltration is generally

more marked on the antero-lateral surface of the cord than on the posterior, though it has been seen all round in the lower part of the sacral region. It is usually less evident in the higher levels of the cord, but has been traced as far as the posterior end of the fourth ventricle and even to the optic chiasma. In the three cases I have examined the great majority of cells contained in the pia arachnoid are of the mononuclear type; a smaller number show the various intermediate stages between the lymphocytic and the plasma cell characters. Only a very small percentage of other cells are to be seen and among these are a few polymorphonuclear leucocytes. Wickman, Dauber, Bickel, Sherman and Spiller, Goldscheider, Williamson, Bulow-Hansen and Harbitz have all found the meninges infiltrated with round cells in cases which have died within a short period after the onset of the disease. That it is not a feature only of fatal cases is shown, as Wickman mentions, by the fact that lymphocytes have been found in the cerebro-spinal fluid during life in non-fatal acute cases. In the case under the care of Dr. Hood, to which I have already referred, a lumbar puncture during life showed the presence of 95 per cent. of lymphocytes in the cerebro-spinal fluid.

Cellular infiltration of the grey matter.—Under this heading I shall refer, not to the cells of the vessel walls which I have already described, but to the masses of cells scattered more or less irregularly throughout the grey matter, particularly, but not exclusively, in the anterior horns. This part of my subject presents great difficulties, for it is one thing to describe the cells which can be seen in these regions and quite another to give them a name or to suggest their origin. Two sources of error may be mentioned; in the first place it is often impossible to distinguish between a small round neuroglial cell and a lymphocyte; in the second place, it is obvious that many cells are proliferating or have undergone changes comparable to the swelling and chromatolysis and excentration of nuclei which are prevalent in the ganglionic nerve cells in this inflammatory process—changes which render them quite devoid of their characteristic features and often unrecognisable. Making due allowance for these facts there appear to be the following cells present in the tissue.

1. Large and small Deiters's cells of the neuroglia, a few of which present their normal characters but the majority of which are altered. Some are swollen and contain one or two large vesicular nuclei but retain some portion of their processes. Others have lost all processes, are swollen, rounded or oval or irregular in shape, and contain eccentric, lobulated, or multiple nuclei. It is probable that many of them are on their way to become compound granular cells, the fat-scavengers in the process of disintegration, which form a prominent feature in slightly later stages of the disease.
2. Small rounded neuroglial nuclei with a thin rim of protoplasm. Some of these are also altered, the nuclei swelling and becoming more vesicular with fewer or more widely separated chromatin granules. The cells of this class are often indistinguishable from the lymphocytic type.
3. Cells which resemble lymphocytes and are probably identical with the cells in the perivascular sheath from which they have wandered. As in the adventitia of the

DESCRIPTIONS OF ILLUSTRATIONS ON PAGE 787.

Fig. 1.—Twelfth dorsal segment of a case of adult acute poliomyelitis fatal within 36 hours of the onset of paralysis. The grey matter stands out more prominently than normal on account of the cell proliferation which has taken place, and the chief vessels of the white matter are also picked out owing to the cellular infiltration of their adventitial sheaths.

Fig. 2.—The cells of Clarke's column and the inflammatory exudation around in a case of acute poliomyelitis within 36 hours of the onset of paralysis. The nerve cells are swollen and chromatolytic, with excentric nuclei.

Fig. 3.—Reproduction of photograph of a vessel in the posterior median septum in a case of acute poliomyelitis of five days' duration, showing the intense infiltration of the adventitial sheath.

Fig. 4.—Diagrammatic drawing to show the cells lining a very fine vessel in acute poliomyelitis.

Fig. 5.—The reproduction of photograph shows the cellular infiltration of the meninges on the anterior surface of the cord especially around one of the anterior root bundles.

Fig. 6.—Cells of grey matter in acute poliomyelitis stained by the Heldenheim method. A, Small nerve cell with encroaching migratory elements. B, A mesodermic connective tissue cell. vessel walls and in the meningeal interspaces, so here one can recognise the deeply stained chromatic rounded nucleus with little or no visible cytoplasm, similar nuclei with a definite cell body and nuclei lying excentrically in a larger cell of oval or oblong shape. The latter may be regarded as plasma cells. 4. A few definite polymorphonuclear cells can be detected and there are other larger cells which may or may not be elements of the same type which have undergone swelling and other changes. In any case polymorphonuclear cells are certainly not numerous. 5. In most sections connective tissue cells of mesodermal origin are to be observed even when no vessel or capillary is seen in their neighbourhood. It is possible that these are either wandering cells or that the section has traversed the adventitial sheath of a vessel tangentially. Endothelial cells are also to be seen and their presence may be explained in a similar manner.

Excluding all the cells I have described there are still a considerable number which it is difficult to classify and for this reason it is impossible to gauge accurately the relative proportion of the various elements. My general impression is that neuroglial proliferation and lymphocytic (using the word purely with regard to morphological character and not in relation to origin) infiltration are the most prominent factors in the production of these cell masses. This view is more or less in accordance with that of several other observers, but Schmaus in a typical case of acute poliomyelitis, which he describes under the misleading and composite name of "acute hæmorrhagic myelitis, myelitis of the bulb, and Landry's paralysis," interprets the cellular infiltration in a different manner. He maintains that there is as much polymorphonuclear emigration as is seen in acute inflammatory conditions of other organs, although he recognises the lymphocytic and other varieties as well. Nissl, on the other hand, regards inflammatory processes in the central nervous system as on a different plane to those of other tissues. According to his view the perivascular adventitial sheath forms a biological boundary line between the mesodermal and ectodermal tissues and inflammation is generally represented by an infiltration of this sheath. Only in exceptional circumstances when the tissues are damaged does the nerve substance itself become invaded by mesodermal elements. In the central nervous system the neuroglial cells largely take on the duties of the polymorphonuclear leucocytes.

Wickman does not support this view of Nissl and inclines more to that of Schmaus, although he finds difficulties in accepting either the one or the other. From my own observations it appears to me probable that the round cell infiltration both of vessels and tissues is a prominent characteristic of acute inflammatory processes in the nervous system and that polymorphonuclear exudation plays a comparatively small part at any rate in the early stages. Moreover, I am inclined to agree with Nissl that the perivascular sheath and lymphatics, on the one hand, may tend to control the exudation, and the activity of the neuroglial cells, on the other, to compensate for its moderate dimensions.

The white substance.—True foci of cells apart from the infiltration of the vessel walls are rarely seen in poliomyelitis and I have found no instance in my cases. Wickman mentions it as occurring exceptionally in his seven acute cases but in no instance was the focus of any great extent. I have already referred to the perivascular infiltration which does not differ essentially in the white from the same process in the grey. Under high powers and with suitable methods of staining it is evident that the neuroglial cells in the white matter are undergoing changes similar to those seen in the neuroglial substance of the grey matter; the Dalters's cells are swollen and contain two or more nuclei; some lose their processes and become surrounded and vacuolated; the small round cells show swelling both of their nuclei and their protoplasm. On the whole, the changes are not nearly so intense as those seen in the grey matter.

The ganglion cells.—The ganglion cells of the anterior horns, of Clarke's column, and of the posterior horns all suffer in varying degrees. Speaking generally, those cells undergo the greatest change which are most closely involved in the inflammatory exudation, but this rule has its exceptions and occasionally remarkably healthy-looking cells are met with surrounded by intense proliferation of the tissue elements. On the other hand, it is most unusual to encounter definite degeneration of ganglion cells which are far removed from the foci of disease. All grades of cell change

are present from early chromatolysis to a condition in which it is difficult to detect the cellular outline or to differentiate the constituent parts. As a rule the nucleolus is the last portion of the cell to retain its structure and its staining reaction. Within the pericellular plicatures are frequently seen small round cells of the lymphocytic or neuroglial variety, some of which are in close contact with the ganglion cell and others perhaps within its substance. How far there is definite neuronophagia it is difficult to say, but certainly extensive degeneration of the cell can take place with little or no invasion of its surface by wandering elements.

The central canal.—In my cases it is impossible to detect changes in the contents or walls of the central canal which are not seen in normal conditions, if due regard is paid to the fact that the cellular infiltration of the grey matter may extend to its immediate proximity. Wickman describes amorphous granular material with occasional round cells within the lumen of the canal but no observer has recorded definite changes in the ependyma.

In summarising the morbid anatomy of acute poliomyelitis as observed by different investigators in cases examined within a few hours or days of the onset of the disease the following points stand out. 1. The most widespread and constant features are, on the one hand, the congestion of blood-vessels and proliferation of the cellular elements of their adventitial sheaths; on the other hand, the absence of all evidence of ante-mortem thrombosis or of changes in the intimal coat. 2. An intense proliferation or exudation of various cells, concerning the origin of which there is a difference of opinion, limited largely to those parts of the central nervous system most freely and generously supplied with blood—that is to say, in the neighbourhood of the rich capillary network of the grey substance of the cord and well-vascularised regions of the brain stem and brain. 3. Round-cell infiltration of the meninges more marked in the lower parts of the cord and on its anterior aspect, but extending in some cases to the intracranial meningeal cisterns. 4. The morbid anatomy of the epidemic and sporadic cases, whether in children or adults, has always proved to be essentially the same in the acute stage.

Time will not allow me to recount to you the many investigations which have been made on the bacteriology of acute poliomyelitis. These observations are of great interest but cannot be regarded as conclusive evidence either of the specificity or non-specificity of the disease. They are not indeed sufficiently complete to prove that in any case the organism which has been isolated has been the causative factor in the disease.

EVIDENCE OF THE INFECTIVE NATURE OF ACUTE POLIOMYELITIS.

On clinical grounds there has now accumulated a mass of evidence supporting the infective nature of acute poliomyelitis, and the fact that the morbid anatomy of the epidemic cases has proved identical with that of sporadic cases gives good reason for the belief that the two conditions are of similar origin and considerable presumptive argument in favour of its specific nature. Some 15 to 20 epidemics of the disease have now been recorded in various parts of the world, the most noticeable being those described by Médin, Bucall, Auerbach, Pasteur, Painter, Mackenzie, and Nannestad.

In London it is difficult to say when there is an epidemic and when there is not, but it is well recognised that the period from July to October is that in which the majority of acute cases are seen, and Batten pointed out the prevalence of the disease in the year 1904. The evidence of the infective nature of the disease can hardly be deemed deficient and it provides, through the epidemics, strong support for the belief that certain forms of encephalitis are due to the same process and the same morbid agent as acute poliomyelitis. The origin of many cases of infantile hemiplegia in this way was long ago suggested by Strümpell and Pierre Marie, and considerable additional testimony has been adduced by Batten, White and Worthington, and other observers. Lamy recorded an interesting old-standing case of atrophic palsy of the right leg in a man who died at 43 years of age. Post-mortem there were found, besides the evidence of old poliomyelitis in the lumbar cord, several old patches of disease in the cerebrum, the largest of which involved the left parietal region.

Sanger and Möbins describe the simultaneous occurrence of a febrile illness in two sisters, one of whom developed a typical spinal paralysis and the other a cerebral hemiplegia.

Marie has contributed a case in which one leg was the seat of a spastic and the other of a flaccid atrophic palsy. Beyer in 1895 recorded the case of a girl who at the age of five years became paralysed on the left side from a cerebral lesion. Epilepsy supervened and the patient died some years later. At the necropsy there were found a porocephaly of the right hemisphere and an old poliomyelitic condition in the left side of the cord. Oppenheim in his text-book of nervous diseases refers to a case of encephalitis of the pons producing facial palsy associated with lumbar and cervical poliomyelitis. E. C. Williams in THE LANCET of 1899 tells us of a case of a school-girl who became paralysed down the right side with aphasia in an acute illness commencing with headache and convulsions. Later examination showed that while the arm was purely spastic the leg of the same side gave evidence of a spinal as well as of a cerebral palsy. Similarly Neurath recounts the history of a child, aged six years, who, during an acute febrile illness, developed right cerebral hemiplegia and atrophic spinal palsy of the left leg. Negro observed the case of an infant, aged 18 months, who in the course of an acute febrile attack associated with convulsions displayed right cerebral hemiplegia and left spinal paralysis. Calabresse has enriched the literature of this subject with two important cases. In the one acute poliomyelitis was associated with ocular palsies, and in the other a spastic hemiplegia, ocular palsies, and atrophic palsy of the other leg were all combined.

There are many cases, therefore, which point to the conclusion that encephalitis of the hemisphere and of the cranial nerve nuclei may have the same origin as acute poliomyelitis, and although the opportunities for examining cases in the acute stage have been scanty we have already seen that in most fatal cases of poliomyelitis the morbid process has extended much higher in the central nervous system than the clinical symptoms at the time of death have suggested. Moreover, Batten and Prickett have had the opportunity of examining the brain in a case of acute encephalitis within a few days of the onset of hemiplegia and have found morbid changes strongly resembling those of acute poliomyelitis.

CLINICAL.

Before entering upon the discussion of the pathogenesis of the disease I must briefly refer to certain clinical features of its acute stage. Generally speaking, the onset of paralysis is preceded by pyrexia, vomiting, convulsions, general malaise, and pains in the head, neck, back, and limbs. In the more fulminating type of case rigidity of the muscles of the neck and back has been noted in the early stages and cerebro-spinal meningitis has been suspected. Just as in the specific fevers, the constitutional symptoms of the infant differ in certain respects from those of the adult. Vomiting and convulsions are more associated with the infantile cases than with the adult although marked vomiting was a prominent feature in the case of a youth, aged 21 years, recorded by Sherman and Spiller. We are, on the other hand, dependent upon the older cases for our knowledge of the character of the pain in this disease and with them it is usually a symptom of considerable moment. They generally complain in the first instance of pain in the head, back, and limbs, of a sharp or burning character, but both before and after this has subsided a most noticeable feature is the distaste for passive movement. This is confirmed by most mothers who have nursed children in the early days of the disease and the fact that the children cannot bear to have their limbs handled is not an infrequent excuse for meagre ablations. We may, I think, distinguish two types of pain: (1) spontaneous temporary pains in the back, head, and limbs in the early hours of the disease, and (2) the pain produced by movement (reflex pains) generally lasting for a few days even after the temperature has subsided. These facts are in harmony with the anatomical data. As we have seen, an intense congestion of the vessels of the central nervous system together with early proliferation of cells in the perivascular sheath and in the meninges are the most widespread and earliest evidences of the acute irritative process.

From the motor aspect one of the characteristics of acute poliomyelitis is the fact that the initial paralysis is always more extensive than the residual in those cases which survive. If we analyse this more closely in relation to severe partially paralysed, perhaps only for a few hours or a day or two; others show atrophy and the reaction of degeneration

but yet make a comparatively rapid recovery in the course of some weeks or months; finally, there are those which never regain power or in which only a few fibres respond to long and persevering treatment. Here, again, we have anatomical analogues. There are anterior horn cells which resist the morbid influences at work and which, while showing no striking structural alterations, may well undergo some temporary derangement of function. There are cells which show what I have described as the early and moderate type of degeneration but which are capable of restoration, and, finally, there are whole groups of cells which, either entirely or with only one or two exceptions, are irretrievably swamped and destroyed in the surrounding exudation.

One more clinical fact about which little has as yet been written. Since Babinski supplied us about ten years ago with a delicate test for the healthy or unhealthy condition of the pyramidal fibres of the cord, it must have happened to you, as it has on several occasions to me, to have obtained an extensor response on eliciting the plantar reflex in cases of acute poliomyelitis. It is, of course, in only a small number of severe cases that the muscles moving the toes are left intact and that this test is therefore applicable; on the other hand, a careful distinction has to be drawn between a pathological extension and an infantile response. Making due allowance for these facts, there is still a small percentage of cases in which definite evidence of pyramidal tract involvement is forthcoming. I have seen several such cases in children and at least one in an adult to which I will shortly refer. Some years ago I saw a young man, aged 22 years, who during August developed a typical attack of acute poliomyelitis. On my first examination, about ten days after the onset, I found that both the flexors and extensors of the right knee and the flexors of the left knee were powerless, while there was only slight weakness below the knee in either leg. On this occasion the right knee-jerk was absent, the left knee-jerk was present, and neither plantar reflex was obtained. A week later the movements at the ankle- and toe-joints were practically restored and I obtained a well-marked extensor response in both feet; the right knee-jerk was still absent and the left was more brisk than normal.

We have already seen that the white columns of the cord, particularly the antero-lateral, suffer to a moderate extent in the disease, and the marked swelling of the axis cylinders and myelin sheaths noted by all observers in the acute stage sufficiently explains this symptom of organic change in the pyramidal system—a symptom which, I believe, is in some cases only of transient duration.

Another clinical point is worthy of note. In the epidemics and in the family cases, like those of Pasteur and of Bulow-Hansen and Harbitz, other members of the household have been taken ill at the same time without developing paralytic phenomena. There is evidence, therefore, of the existence of what may be termed abortive cases. On the other hand, there is a great probability that many cases of acute generalised poliomyelitis occur in young infants and rapidly prove fatal without being recognised. The child observed by Drummond who died within six or seven hours from the onset is suggestive of this being the case.

PATHOGENESIS.

We are now in a position to discuss the various theories which have been advanced to explain the nature of acute poliomyelitis. That view, which originated from the examination of long-standing cases and which indicated a primary degeneration of the anterior horn cells and an entirely secondary change in the interstitial tissues, cannot at the present time be taken seriously. The examination of early cases has been its death-blow. The theory which it is most convenient to take second is the so-called "vascular" one, originally introduced by Pierre Marie and supported by Batten in recent years.

I must say at once that by a number of writers the term "vascular" is used erroneously, or at any rate in a way which is apt to lead to a confusion of ideas. The fact that within an area of tissue the vessels are engorged with blood and surrounded by numerous cells which have emigrated from the blood stream or proliferated *in situ* and that there are serous exudations or hemorrhages, is not in itself sufficient reason for calling the lesion a vascular one. It is generally accepted that all the demonstrable phases of inflammation have to do with the vessels and the blood—in fact, inflammation can only be recognised by vascular phenomena. Thus, dilatation of the vessels, acceleration and

then slowing of the stream, followed possibly by blood stasis and exudation of lymph and cells are the text-book criteria of inflammation. Again, we are taught that three things may happen as a final result—namely, resolution, suppuration, or necrosis due to complete blood stasis and thrombosis. We recognise, therefore, that thrombosis of vessels may occur as a result of inflammation, but the origin of a thrombosis in that way should not incite the observer to call the whole process "vascular." In acute poliomyelitis thrombosis of vessels may be present at the time of examination some time after the onset. Is this thrombosis a primary lesion or is it secondary to an inflammatory process? On this point Batten expresses a decided opinion when he states "that the condition is due to a primary thrombosis of a branch or branches of the anterior spinal artery supplying the grey matter of the anterior horn." Head and Campbell have said, "If by 'vascular' is meant that the disease is directly secondary to occlusion or interference with a vessel we deny its correctness; if, on the other hand, it is meant that the vessels play an important part in the general inflammatory process it is a platitude," and they go on to say that many observers have occluded the vessels of the spinal cord and brain without producing inflammatory changes or hæmorrhages. In answer to this Batten says, "It must be remembered that obliteration of a large vessel is by no means necessarily comparable to the condition which is produced when thrombosis occurs in smaller vessels. Far more to the point are the experiments of Prévost and Cotard (although performed many years ago) with regard to the changes which take place in an infarcted area. By the means of fine tobacco seeds they succeeded in producing infarcts in various organs and they proved by their experiments that congestion, hæmorrhage, and exudation of the cells were the only results of obliteration of small vessels."

Now, the argument that the experiments of Prévost and Cotard prove the dependence of the inflammatory changes on the obliteration of vessels will not, to my mind, hold good. Conclusive evidence on this point is supplied by the work of Hoche published in 1899. This investigator injected into the lumbar arteries of dogs aseptic material in the form of lycopodium granules, pollen of *Typha japonica*, granules of maize starch, and kamala glands. By these means he produced lesions in that part of the spinal cord supplied by the arteries which had a strong resemblance in certain respects to those of poliomyelitis. The various materials injected were responsible for the formation of numerous embolic softenings or infarcts within the cord of sizes varying with the calibre of the vessel in which the particle became lodged. In addition to the production of necrotic areas, however, there was also evidence of tissue reaction to the chemical irritation of the emboli in the shape of marked cellular infiltration of the adventitial sheath of the vessels both in the white and in the grey matter, identical, so far as one can see, with that found in acute poliomyelitis. The most important fact is that although the infarct production was the same whatever species of emboli were introduced, the degree and intensity of the tissue reaction varied with the chemical nature of the emboli. For instance, the most marked reaction followed the use of kamala glands, less reaction that of the pollen of *Typha japonica*, and little, often no, reaction that of lycopodium granules. It is evident, on these grounds alone, that mechanical blockage of vessels cannot of itself produce the tissue reaction, but the fact is still further emphasised by Hoche's finding that no tissue reaction results unless the source of chemical irritation is brought into close relation with the tissues themselves. If a branch of the anterior spinal artery was blocked by one of the larger emboli just before it entered the grey matter no inflammatory action was produced; on the other hand, when the irritating particles were distributed through the finer branches and capillaries cellular proliferation was induced in the surrounding tissues varying with the chemical nature of the substance used.

What applies to the vegetable material used by Hoche must apply at least equally to the tobacco seeds of Prévost and Cotard and the only evidence in favour of the view that perivascular round cell infiltration can be the result of simple thrombosis or embolism falls at once to the ground. But perhaps the best answer to the "primary thrombosis" theory is that no observer who has examined the cord during the first few days after the onset of illness has found thrombosis of any of the vessels. For these and many other reasons into which I will not enter now I am quite unable to support the

"primary thrombosis" theory concerning the origin of acute poliomyelitis and it is equally clear from all I have already put before you, both from the observations of others and from my own cases, that whatever agent induces the perivascular infiltration does its work impartially on the vessels radiating through the white columns of the cord and the various vessels supplying the brain stem, as well as on the branches of the anterior spinal artery. Wickman, who has had unequalled opportunities of studying the early stages of the disease, is emphatic on this point.

It may, and probably will, be argued that all cases of poliomyelitis have not an identical pathological basis. It will be said there are cases in which the onset is extremely rapid and associated with little or no constitutional disturbance and with no pain. With these cases I am familiar, but there are one or two points to bear in mind in this connexion. In the first place, there is an enormous variation in the degree of constitutional disturbance with every acute specific fever. We are all familiar with this in the case of measles, chicken-pox, and diphtheria, and we recognise an ambulatory form of typhoid fever, but we do not for this reason exclude the cases with little or no pyrexia, with no loss of appetite, or headache or pains, from the category of those diseases. In the second place, it must be remembered that the paralysis is almost an accidental result of the disease depending on the involvement of the anterior horn cells by the inflammatory exudation, and that the latter may only here and there be sufficiently intense to affect the former. A considerable amount of widespread subacute inflammation may therefore be present with no, or very little, indication in the way of paralysis or of constitutional disturbance. In the third place, we often have to deal with cases in which the acute stage is a matter of more or less remote history and the reliability of witnesses on these points is proverbially insecure. At the same time, after making due allowance for those sources of error, I am prepared to admit that there are a very limited number of cases in which the suddenness of onset and the narrow limitation of the paralysis do suggest the possibility of a true vascular lesion of the cord. I have, indeed, suggested elsewhere the same possibility in relation to the occurrence of certain peripheral palsies limited to the distribution of a single nerve root. On the other hand, I know of no confirmation on histological evidence of either the one or the other if cases of hæmatomyelia are excluded.

Having now rejected two of the theories which have been put forward for the explanation of acute poliomyelitis, I think we are in a position to say that the process is an inflammatory one and probably due to the influence of some micro-organism or its toxin. There are two questions, at least, still to be answered—1. Has the toxin a special affinity for any particular tissue? 2. Is the toxin brought into relation with the tissues of the central nervous system through the medium of the blood or of the lymph, if, indeed, a fair distinction of this kind can be drawn?

With regard to the first question we are at once struck by the fact that the most intense reaction is found in association with those parts where ganglion cells are most numerous, especially in the spinal cord. Does this indicate a chemical affinity on the part of the poison for the true nervous elements? Not necessarily because, as I have already pointed out, the regions in which nerve cells are present are also the regions where blood-supply and capillary network are always the richest. The same parts, therefore, are most freely bathed with blood, probably with lymph, and most easily accessible to the poison carried by these fluids. On the whole, the evidence favours the view that there is no special affinity on the part of the toxin for the nerve cells and that the latter suffer chiefly through the inflammation of the tissue which supports them. The healthy condition of cells away from the foci of inflammation and sometimes in their immediate neighbourhood points strongly in this direction.

The other alternative is that the poison exerts a special influence on the neuroglial tissue and in favour of this there is a good deal to be said. It would explain why the central nervous system suffers and the peripheral nerves escape. It is in harmony with the neuroglial proliferation, more marked in the grey matter where the poison is brought into closer contact with the tissues, less marked but still evident in the white matter where the capillary blood-supply is poorer and where the neuroglial substance is broken up by columns of well-myelinated nerve fibres. If we adopt the view that the poison has this

finity for the neuroglia and exerts it from the blood stream we may well regard the perivascular and meningeal infiltration as evidence of a protective process, successful to a great extent in the white matter but unable always to cope with the accumulation of toxic forces in the vascular grey matter. Whether it is justifiable or not to assume a particular relationship between the poison of acute poliomyelitis and the neuroglial tissue of the central nervous system, it is clear that in some way the destruction of the ganglion cells is the result of the inflammation of the interstitial substance and not due entirely to toxic influences.

Is the infection of the nervous system hæmatogenous or lymphogenous? The most striking evidence in favour of the hæmatogenous infection is afforded to my mind by the experiments of Hoche to which I have already referred. In one of his illustrations you will see that the general appearances of the section of the cord are similar to those of acute poliomyelitis, if we exclude the extensive necrosis of the white as well as grey matter produced by the blockage of the vessels, and we know that in this case the poisonous material was introduced through the blood stream. Moreover, the finer histological details as described by Hoche in his paper bear a strong resemblance to those of the disease we are considering.

Wickman is the chief supporter of the lymphogenous origin of the infection in poliomyelitis and he certainly urges the claim on strong grounds. The inflammation in the meninges and perivascular lymph channels and the not infrequent spread of the disease in an upward direction are points in its favour, but he has not given us any clear evidence of infection of the central canal in the cases he has examined. The same author has drawn attention to the general resemblance of the morbid processes in the central nervous system to those found in rabies either of man or the lower animals. If one examines the drawings made by Sir William Gowers for the Transactions of the Pathological Society in 1877, representing the changes in the medulla in four cases of hydrophobia which he had examined, one finds a picture which would do well for what other observers, as well as myself, have found in fatal cases of poliomyelitis. There are the same distension of blood-vessels and the same infiltration of perivascular lymph spaces with cells which are regarded as leucocytes; there are, too, the foci of round cells in the bulbar nuclei and in the formatio reticularis. Gowers mentions that similar changes are present in the spinal cord in some cases, and later writers have regarded the inflammatory condition of the latter as characteristic of rabies, whether it is accidental or experimental in origin. They have described the perivascular infiltration in the white as well as the grey matter, the foci of normal cells in the cornua, the serous exudation around vessels, and the various degrees of degeneration in the ganglion cells. Schaffer believes that the greatest intensity of pathological change was present in that part of the cord which innervated the region of the source of infection, but this is not confirmed by Babes. Wickman has reproduced a drawing from the monograph of Hogyes showing under low magnification the general appearance of the sacral cord of a child who had been bitten and infected in the thigh, and uses it as additional evidence in favour of the lymphogenous origin of poliomyelitis. The anatomical similarity between rabies and poliomyelitis is rendered still more interesting by the fact that the paralytic form of rabies, which is by no means uncommon, may present clinical features indistinguishable from those of acute poliomyelitis. The well-known case published by Bristowe and Horsley of hydrophobia resembling clinically an acute ascending paralysis showed a morbid anatomy which would readily pass for an acute poliomyelitis (although not for a Landry's paralysis), and the distinction was only confirmed by the fact that rabies was reproduced in animals by inoculation from the cord of the patient. However interesting the points of similarity between rabies and poliomyelitis may be, their use as evidence of the lymphogenous origin of the latter must be delayed until the former has been definitely shown to result from that mode of infection.

Against the view that the cord in poliomyelitis is infected through the lymphatics of the peripheral nerves must be ranged the experiments of Homen to which I referred in my first lecture. It was shown there (1) that the entry of organisms and toxins into the spinal cord was effected chiefly along the various septa within the lymph channels of the radial vessels and along the anterior, and more especially the posterior, roots: (2) that within the spinal cord and

its membrane the infection was carried upwards mainly between the meninges and along the central canal; and (3) that the changes within the cord were somewhat patchy and irregular, affecting the grey and white matter alike and especially the region of the posterior median septum. These facts do not tally with the lesions of poliomyelitis and have much more in common with those of ascending myelitis.

Before passing on to my final conclusions I must say a word or two with regard to the specificity of acute poliomyelitis. No dogmatic statement can be made on this point with the bacteriology of the disease in its present extremely incomplete and unsatisfactory position; but the epidemic phases of the disease and the lack of success which has attended efforts to produce experimentally, with the ordinary pathogenic organisms, any condition comparable to that of poliomyelitis are two important points in favour of the view that it is a specific disease. The argument that it frequently follows measles, scarlet fever, influenza, and other specific fevers cannot outweigh the other facts or, indeed, be regarded very seriously. There are plenty of instances of acute specific fever following quickly on the heels of another without any suggestion forthcoming that the latter condition is a result of the earlier one.

I cannot help feeling strongly that acute poliomyelitis will, before many years have passed, be included in the category of the specific fevers. It has the constitutional disturbances, the age incidence, the seasonal exacerbations, the sporadic and epidemic types, the immunity from second attacks, associated with the obscurity as to its bacterial origin, which are shown by measles, scarlet fever, and others, and the severe inflammatory lesions limited to particular tissues which are met with in typhoid fever, diphtheria, and variola, as well as other members of the same category.

The following conclusions appear to me justifiable concerning the disease:—1. It is an acute specific fever occurring sporadically and epidemically, differing from many others but resembling some—variola, for instance—in the facts that its lesions may be discrete or confluent and that its results may be permanent. 2. Its essential lesion is an inflammation of the interstitial tissue of the central nervous system due to the presence of micro-organisms or their toxins probably in the blood (but possibly in the lymph) circulating within that system. 3. The fact that the grey matter suffers more than the white matter is explained by the greater vascularity of the former and the resistant character of the component parts of the latter. 4. The same morbid process underlies some cases of encephalitis both of the brain stem and the cerebrum, among which may probably be included many examples of infantile hemiplegia. 5. The bacteriology is at the present time practically an unknown quantity. Bacteriological investigation of the blood as well as of the cerebro-spinal fluid is indicated, and more complete examination of other organs, especially of the intestines.

UNIVERSITY OF LONDON.—An election to the Senate of the University of London took place on March 19th. There were two ballots; at the first 243 voted, the figures being 114 for Dr. L. E. Hill, 104 for Dr. J. R. Bradford, 102 for Dr. J. Kingston Fowler, 95 for Dr. H. A. Caley, and 48 for Dr. Norman Moore. Dr. Norman Moore did not proceed to the second ballot, when 227 voted, and the figures were found to be 126 for Dr. Hill, 125 for Dr. Caley, 100 for Dr. Bradford, and 99 for Dr. Fowler. Dr. Hill and Dr. Caley were therefore declared to have been elected to the two vacancies on the Senate.

ROYAL FREE HOSPITAL.—The Duchess of Albany, attended by Lady Evelyn Moreton and accompanied by Mrs. Harkness, visited the Royal Free Hospital, Gray's Inn-road, on the afternoon of March 15th, where she was received by Dr. Harrington Sainsbury, the senior physician; Mr. Conrad Thies, the secretary; and Miss Cox-Davies, the matron. Her Royal Highness visited the wards, nurses' quarters, and various departments of the hospital and expressed her great satisfaction at the many structural and other improvements recently carried out and her approval of the proposed erection of two new operating theatres which are urgently needed to meet the greatly increased surgical work of the hospital. Before leaving Her Royal Highness signed the visitors' book and partook of tea in the matron's sitting-room.

The Hunterian Lectures

OR

THE RENAL FUNCTION IN ITS RELATION TO SURGERY.

Delivered before the Royal College of Surgeons of England,

By J. W. THOMSON WALKER, M.B.,
C.M. EDIN., F.R.C.S. ENG.,

HUNTERIAN PROFESSOR OF SURGERY, ROYAL COLLEGE OF SURGEONS
OF ENGLAND; ASSISTANT SURGEON TO THE NORTH-WEST
LONDON HOSPITAL AND TO ST. PETER'S
HOSPITAL FOR STOMACH.

LECTURE II.¹

Delivered on March 4th, 1907.

THE ESTIMATION OF THE FUNCTION OF ONE KIDNEY.

MR. PRESIDENT AND GENTLEMEN,—In my first lecture I endeavoured to show what means had been adopted to ascertain the value of the combined function of the kidneys. I shall now pass to the consideration of the methods at the disposal of the surgeon in estimating the function of one kidney. When one kidney is diseased and it is accepted that its function is seriously impaired or totally destroyed the question of prognosis and the decision in regard to surgical interference and its extent will in a considerable majority of cases depend upon the view which the surgeon takes in regard to the functional activity of the second kidney. I shall briefly review the methods upon which until a recent date the surgeon relied for the data on which to base his judgment in this matter.

Where one kidney is obviously diseased the patient may show symptoms of failure of the renal function and thus betray the reduced activity of the second kidney. With these symptoms before him the surgeon will be able to decide whether he will take the risk of advising surgical interference and how far this may be carried. But it is in the case where general symptoms of renal failure are absent that more information is desired in regard to the functional power of the second kidney. The surgeon has hitherto had to depend upon the presence of local signs of disease of the second kidney, upon his experience of the pathology of such diseases, and lastly upon statistics. There may be enlargement, pain, and tenderness of the organ, but these do not give unquestionable proof that the kidney is seriously diseased. The x-rays may give valuable aid in some cases of calculous disease. Extensive shadows in the second kidney may indicate that the margin of renal tissue is too small to maintain the function, or, on the other hand, the absence of shadows will show that calculi are not present in the second kidney.

But these form only a small number of the cases that are presented for consideration. The real difficulty arises when there are no general symptoms of renal failure and there are no local signs of disease of the second kidney. It cannot be said in such a case that the absence of signs of disease are a proof of the health of the second kidney, for experience has abundantly shown this to be erroneous.

The statistics which have been compiled with regard to the bilateral incidence of various renal disorders may be used in this service. Some of these are seen in the following list:—

Statistics of Solitary Kidneys and Bilateral Renal Disease.

Solitary kidneys (one kidney atrophied)	6 in 15,904, 1 in 2650 (Morris).
Small, shrunken, or wasted	59 in 8178, 1 in 138 (Morris).
Malignant growths, bilateral	12 in 118, 1 in 10 (Kelysack).
Polycystic kidney, bilateral	150 in 191 (Kidster, collected). 25 in 28 (Dickinson, collected). 65 in 68 (Lejars, collected). 4 in 4 (Israel). 3 in 7 (Morris).
Calculus, bilateral	38 in 76, 50 per cent. (Legueu). 90 in 764, 11.78 per cent. (Kistner). 21 in 83, 25.3 per cent. (Torrès).
Pyelonephritis, bilateral	59 in 71, 83 per cent. (Weir).
Tuberculous disease, bilateral	43 in 81, 53 per cent. (Hedberg and Oppenheim). 106 in 205, 51 per cent. (Pulei).

¹ Lecture I. was published in THE LANCET of March 16th, 1907, p. 711.

Statistics have, however, only a limited value. It will be seen by referring to the figures quoted above that renal growths are unilateral in over 89 per cent. of published cases. This percentage is therefore accepted as a guarantee that in removing a kidney containing a renal growth little or no risk is run of the patient having submitted to a useless operation from the presence of a second tumour in the remaining kidney. Again, it is known that the ratio of solitary kidneys is 1 in 2650 cases and that a kidney may be removed with but small chance of the patient being dead from uræmia in a few days from the removal of his entire urine secreting apparatus. Apart from such unusual cases, however, there is a large number of patients who suffer from some renal disease which is notoriously bilateral in its later stages. These cases include certain forms of renal calculus, tuberculous disease, and suppurative diseases of the kidney. In operating upon the obviously diseased kidney in such conditions and especially in proposing removal of the organ a certain risk is undertaken.

I have collected from the literature 75 cases of operation upon one kidney where uræmia or anuria commenced within the first few days after operation. Of these 26 (34.6 per cent.) were calculous, 17 (22.6 per cent.) tuberculous, and other suppurative conditions were present in 13 (17.3 per cent.). Nephrotomy was performed in 27 cases and nephrectomy in 48. There was no second kidney in five. The second kidney was atrophied in seven, the seat of nephritis or degeneration in 18, calculus in 12, pyo- and hydronephrosis in nine, tuberculous in six, and new growth in two. It is certain that in some of these cases operation would not have been performed had the state of the second kidney been known.

CYSTOSCOPIC EXAMINATION OF THE URETERAL OPENINGS.

The discharge of urine or other material from the ureteric orifice might be expected to give valuable assistance in the investigation of renal disease, and this is the case where the localisation or diagnosis of an obscure disease is the subject of inquiry. But when the diagnosis is already made and the sole object of investigation is to measure the functional activity of the kidney the information gained by the examination is frequently disappointing.

The absence of a periodic discharge of urine does not signify that no kidney is present or that the functional power of the kidney is destroyed. It not infrequently happens that no discharge of urine is observed for a considerable time when there is every reason to believe that the kidney is healthy. Such periods of functional inactivity are the result of nervous influences. Where one kidney is absent it does not of necessity follow that the ureteral opening is also absent. In a case recorded by Jolly² the right kidney was absent. On the right side of the trigone there was a ureteral opening into which a probe could be passed for 1 centimetre and beyond that there was a fibrous band 13 centimetres long. Usually, however, when one kidney is congenitally absent there is no ureteral opening on that side. The remaining ureter may be normal in position or it may be displaced. In 18 cases where one kidney was absent the corresponding ureter was also absent in 12, and it was specifically stated that the ureteral orifice was absent in four of these.³ It will sometimes happen from various causes that there is a difficulty in finding one ureteric orifice in cases where both kidneys are present.

A copious efflux is not a guarantee that the function of the kidney is healthy. The polyuria of advanced interstitial nephritis and of waxy disease may be observed on the side of the second kidney in renal surgery. A purulent or bloody urine is no measure of the renal function, however important it may be in diagnosis. I have never seen a "solid efflux" of blood and debris such as Mr. E. Harry Fenwick describes,⁴ but I have met with a case of hæmaturia in which an irregular greyish spongy-looking clot projected from the left ureter (Fig. 14). The renal function was not seriously impaired. It is a different matter when a worm of semi-solid waxy pus is slowly expressed at intervals from a reddened ureter (Fig. 15). I have notes of two such cases. There had been symptoms of renal trouble for eight and 11 years respectively and in each case the kidney was a large thick-walled pyonephrosis containing much semi-solid pus,

² Soc. Anat. de Paris, Jan. 9th, 1886.

³ In these cases the genital system was either normal or no abnormality was mentioned in 15. There was general malformation of the external genital organs in one case and abnormality on the same side as the absent kidney in two.

⁴ Ureteric Mesotocopy in Obscure Diseases of the Kidneys, 1903.

débris, and calculi. This form of ureteric discharge is significant of a functionless kidney.

I have met with four examples of a condition which Mr. Fenwick has described as the "dragged out" ureteric orifice.

FIG. 14.

Ragged greyish blood clot projecting from left ureter after severe renal hamaturia.

Of the condition this observer says: "It affords the most conclusive *cystoscopic* evidence that we possess of the partial destruction of a small, often unfeeleable, kidney by tuberculosis." The orifice is displaced upwards and outwards and

FIG. 15.

Mass of semi-solid pus expressed at intervals from left ureter. Case of left pyonephrosis.

lies in the depth of a tunnel-like depression. In the four cases that came under my observation there was advanced tuberculous disease of the kidney in all. In one case the hypertrophied inter-ureteric bar which formed a ridge running along the floor of the tunnel was dragged in and out at

FIG. 16.

"Dragged out" ureter in case of renal tuberculosis.

each respiratory movement almost like a piston; in another no respiratory movement took place but pressure on the kidney caused a violent tug at this ridge of muscle.

CHROMOCYSTOSCOPY.

A method of cystoscopic estimation of the renal function has been suggested by Vallicher and Joseph.⁵ An intramuscular injection of four cubic centimetres of a 4 per cent. solution of indigo carmine is made. Elimination commences in 20 minutes, reaches its height 30 minutes later, and has ceased in two hours. The authors claim that the examination of the ureteral openings and the observation of variations in the depth of staining of the urines during the elimination will afford an approximate idea of the functional value of the two kidneys (Fig. 17). Similar observations had previously been made with methylene blue. This method is preferred by some (Hartmann, Leguen) to the results of ureteral catheterisation. The two methods do not, however, lend themselves to comparison. Differences in the depth of staining of the urine of each kidney can be observed by either method.

FIG. 17.

Chromocystoscopy. The left ureter is shown at the moment when a jet of urine stained with indigo-carmin is being expelled.

but much more accurately in collected separate urines than by watching the momentary jet from the ureteral orifice. But in addition to this the chemical and microscopical analysis of the separated urines gives invaluable information that cannot be obtained by chromocystoscopy. At the best it is a ready clinical test of the presence or absence of a ureteral fistula and from the opacity of the jet some idea may be gained of the function of the kidney. As a means of localising the position of the ureters in difficult cases and of making observations on the renal secretion where catheterisation of the ureters or separation of the urines is impossible it may play a minor rôle.

METHODS OF OBTAINING THE URINE OF EACH KIDNEY SEPARATELY.

It has been the ambition of surgeons almost since the date of the first nephrectomy to obtain the urine of each kidney separately for examination. Dr. Tuchmann⁶ perfected his apparatus five years after Simon's nephrectomy and other methods were published in rapid succession. So far as the earlier attempts were concerned the chief source of interest was the localisation of disease to one or other kidney. Other means have been introduced and perfected which have to some extent, although not entirely, replaced this use of the separation of urines, and its chief sphere of usefulness at the present time is the examination of the urines in order to estimate the function of these organs.

It is beyond the scope of these lectures to trace the evolution of the methods of separation of the urine from each kidney, nor shall I discuss the technique or dwell upon the arguments for or against this method of investigation. We are concerned here with the results obtained by different methods of testing the renal function.

THE EXAMINATION OF THE URINES OF THE TWO KIDNEYS.

The cumulative evidence of many series of careful examinations have provided a quantitative average for the combined output of the two kidneys. With the separation of the urine into the output of each kidney the necessity for a new standard for comparison arose. It was not sufficient to divide the total output by

⁵ Münchener Medizinische Wochenschrift, 1903, p. 2023, and Deutsche Medizinische Wochenschrift, 1904, p. 536.

⁶ Wiener Medizinische Wochenschrift, 1874, pp. 21-22.

two in order to indicate the work of one kidney, for Landois, Hermann, Ludwig, and others have shown the unequal physiological value of the kidneys at a given time in animals.

For reasons that I shall presently relate the urine of the second kidney, when one is diseased, cannot always be used as a normal standard with which to compare the work of the diseased organ. An independent normal standard must therefore be set up to show the average normal output of one kidney. This standard has been provided by the work of Albarran.⁷ According to this observer no regular alternation is observed in the work of the two kidneys, but when the secretion of each kidney is collected during six or 12 hours it is found that each has performed nearly the same work. One may consider as practically healthy a kidney which secretes a urine like the following in 24 hours:—

Quantity		600 to 700 cubic centimetres.
Urea		12 to 15 grammes.
Chlorides		5 to 6 "
Δ		-1.30° to -1.50° C.

If the time during which the urine is collected is only two or three hours the figures are less reliable. It is then necessary to study the urine at a time when digestion is not going on and when the individual has not drunk anything for several hours.

Albarran gives the following as an analysis of urine collected from one kidney during one hour under these conditions when both kidneys are healthy:—

Quantity		50 to 60 cubic centimetres.
Δ		-1.20° to -1.50° C.
Urea		12 to 17 grammes per litre.
NaCl		10 to 12 "

In comparing the function of two healthy kidneys this observer found that when the comparison was made of urine collected during so short a time as a quarter of an hour the difference amounted to as much as from 10 to 30 per cent. in the quantity of urine secreted, but when the examination was extended to one hour the difference was reduced to 10 per cent. The difference in the quantity of urea might be one gramme per litre or might amount to 6.50 grammes. The difference in the quantity of chlorides amounted to 50 centigrammes per litre and might attain five grammes. The diseased kidney usually secretes less urine than its healthy or less diseased neighbour. This will in some manner depend upon the form and extent of the disease. A hydro-nephrotic kidney will pass no urine through the catheter or only a very small quantity during the period of its retention. A pyonephrosis or an extensive pyelonephritis will produce a much reduced quantity. This reduced activity may be thrown into stronger relief by the secretion of an increased quantity of urine by the healthy organ and an erroneous idea of the extent of the disease may be gained by observing the inequality of secretion in such a case. The polyuria may result from passing causes or it may result from compensatory hypertrophy.

But there are frequent exceptions to this statement. The two urines may be practically equal in quantity where one kidney is diseased. Further, as Albarran has pointed out, there may be an exaggerated activity on the part of the diseased organ so that a polyuria may be observed on this side. There may be at the same time an excessive elimination of urinary salts. The urine of the diseased side is often lacking in pigment. This may be observed when the quantity of urine does not show a very great difference from that of the healthy kidney; it is more striking where the quantity of urine is excessive on the diseased side. There is usually a diminution in the quantity of urea, chlorides, and phosphates contained in the urine of the diseased side, and this is greater when the disease is more advanced. The following analysis of the urines from a case of calculous pyonephrosis illustrates this and other points to which I shall refer later.

	Right kidney (diseased).	Left kidney.
Quantity	206.5 c.c.	107.5 c.c.
Specific gravity	1.004	1.011
Δ	-0.18° C.	-0.76° C.
Colour	Pale limpid.	Fairly coloured.
Urea	0.4 per cent.	1.3 per cent.
Uric acid	0.0067 "	0.0150 "
Chlorides as chlorides	0.6977 "	0.1112 "
Phosphates as P_2O_5	0.08 "	0.034 "
Methylene blue	No change in colour.	Appeared 1 hour 50 minutes, green colour, duration 18 hours.
Chromogen appeared	25 minutes, faint green.	25 minutes, deep green.
Phloridzin glycosuria	0.395 grammes.	1.623 grammes.

CRYOSCOPY OF THE TWO URINES.

Changes in the freezing point of the two urines are dependent upon a proportional increase or decrease of the molecular composition of the urine. In order to make observations of any value upon the cryoscopy of the urines a knowledge of the comparative volumes of the urines is necessary. Just as in estimating the total function of the kidneys the volume of urine and its molecular composition change under varying conditions during the day and night, so the composition of the single kidney urine will change, and an attempt to estimate the functional value of one kidney must be subject to similar restrictions. Thus it is necessary to collect the urines by catheters during 24 hours and to examine the mixed specimen, and, further, the observations should be repeated on several successive days. It is evident that such a method of examination is impracticable, so that observations must be made, if cryoscopy is to be used, upon a urine secreted during a much shorter period of time (two or three hours). The variations in healthy individuals, even with a careful control of the solid and fluid intake, are very considerable, and it appears to me to be doubtful whether any trustworthy data in regard to the function of one kidney can be obtained by this method.

Comparative cryoscopy of the two urines will, however, give some information in regard to the difference of function between the kidneys and, if it can be ascertained that one of them is healthy, this may act as a standard for comparison for the other. It must be remembered, however, that the function of the healthy kidney is likely to be depressed from the presence of its diseased neighbour. Usually there is a diminished quantity of urine with a reduced molecular content on the diseased side; occasionally there may be a polyuria with a proportionally greater reduction of molecules. The presence of polyuria or the reverse is not a measure of the functional activity of the kidney, and even where the quantity of urine is included in the formula the large variations are likely to prove a fallacy in the result of the calculation. It is important, also, to note that the healthy or almost healthy kidney may produce an increased quantity of urine. The result may be affected by these factors, so that even when the freezing point, corrected for volume, of the two sides is compared higher figures may be obtained on the diseased side.

When the volume of urine of one kidney is greater and the freezing point shows at the same time a greater molecular content this kidney is functionally more active than its neighbour.

In the lesser degrees of renal disease the cryoscopy figures are not usually altered, but where disease has destroyed a large part of a kidney there is usually a marked difference between the freezing points of the two urines. The variations in the point Δ of the two urines do not follow closely those of the quantity of urea, sodium chloride, and phosphates.

METHYLENE BLUE TEST FOR EACH KIDNEY.

In using methylene blue for the estimation of the function of each kidney it is obviously inadvisable to make observations for the 60 or more hours during which the blue may be expected to be present in the normal state, much less is it expedient to attempt the drainage of each kidney during the protracted elimination that may occur in disease. The accompanying chart (Fig. 18) shows the elimination of blue and chromogen in a case of hydro-nephrosis.

Two of the important points in the elimination of methylene blue by the kidneys may, however, be investigated with a comparatively short ureteral drainage. Observations may be made on the time of appearance of the blue and chromogen and the depth of staining of the secretion as a measure of the quantity of blue eliminated. For this purpose a catheterisation of an hour, or at most two hours, will suffice.

I have selected the following cases in illustration as they indicate the extent of the information that may be gained by this method and show how far the conclusions based upon it were justified.

CASE 1.—The patient was a man suffering from right-sided pyelitis of ten months' duration with an enlarged tender kidney. On the right (diseased) side methylene blue appeared in 60 minutes as a dirty green colouration and the microscope showed pus and renal cells and bacilli. The left ureter gave clear blue urine in 30 minutes which showed no deposit. After nephrotomy the symptoms subsided.

CASE 2.—The patient, aged 48 years, came under my observation at the North-West London Hospital. There was

FIG. 18.

Elimination of methylene blue and chromogen in a case of hydronephrosis. Delay and diminished quantity of blue and delay of chromogen on diseased side (Albarran).

a large, hard left kidney and the right kidney was not palpable or tender. The left (diseased) kidney excreted no methylene blue and no chromogen and the right urine was deeply stained with methylene blue and chromogen in 27 minutes. A large thin-walled pyonephrotic cyst containing masses of calculi was removed. The patient died with symptoms of septic absorption. The remaining kidney (right) was found to be healthy.

CASE 3.—In this case there was a large, hard, irregular calcareous mass in the right kidney and the left kidney was not palpable or tender. There were no symptoms of renal failure except constant thirst. No blue or chromogens appeared in the urine from either kidney. Operation was refused and the patient died from suppression of urine 18 months later. The left kidney was also destroyed by calculi.

CASE 4.—This was another case of calculous pyonephrosis. The right (diseased) kidney passed no blue but a small amount of chromogen appeared. The left kidney passed chromogen in quantity in 25 minutes and blue in 1 hour 50 minutes. The right kidney was found on operation to contain large calcareous masses with a thin covering of fibrous renal tissue. The patient made a good recovery.

An early onset of elimination and a good quantity of blue in the urine were accepted in my cases as a guarantee of the functional activity of the second kidney, whereas the absence of blue and chromogen in the urine of the second kidney was taken as an indication of an inefficient or destroyed kidney. Between the extremes of a well marked blue elimination and its complete absence from the urine of the second kidney there are varying degrees of elimination. In making observations upon such cases the methylene blue method suffers from the disadvantage of a long duration. The drainage of each ureter by catheter during a period of two or three days is impracticable as a routine measure.

Except in such pronounced results as those which I have related the method does not provide sufficiently definite information on which to base conclusions as to the total function of one kidney. But as a means of comparing the work of the two kidneys in a given time it has an undoubted value. If the function of the combined kidneys is estimated at a high value and the separation of the urines shows that the blue is secreted with little delay on either side and in about equal

quantity the active renal tissue is probably distributed pretty evenly between the two organs and is present in good quantity. If, on the other hand, the commencement of elimination is delayed and the total blue excreted is small in amount and by draining each kidney the proportion is found evenly distributed between the two, it would be inferred that a diminished amount of renal tissue was distributed equally between the two organs and for this reason nephrectomy might be contra indicated. When the difference between the two secretions is marked so that the supposed healthy kidney secretes much the greater quantity of methylene blue it will appear probable that the second kidney has already assumed a large part of the renal function and may be trusted to carry it on if the diseased organ is removed. This demonstration of the renal function will be the more striking if the diseased kidney eliminates no trace of blue or chromogen. On the other hand, it is certain that if the second kidney is the seat of latent disease which has hitherto passed unnoticed examination of the urine drawn by catheter from that ureter will give a clue to the presence of the disease which will be strengthened by the use of the methylene blue test. I have not observed as a frequent occurrence the intermittent elimination of methylene blue by the healthy second kidney which Albarran attributes to compensatory hypertrophy.

Before leaving this test an observation may be made in regard to the demonstration of the relief from the renal calculus. In a case of pyonephrosis nephrotomy was performed on August 16th, 1906 and the injection of methylene blue failed to colour the urine or to appear in the discharge from the wound. Chromogen appeared in the urine in one and a quarter hours. Nephrectomy was performed on August 29th and the methylene blue test was again carried out. The dye now appeared as a deep green and the chromogen as a blue-green in the urine in one and a half hours and one hour respectively. The patient made a good recovery. (Fig. 9, Lecture I.)

PHENOLDIN GLYCO-URIA TEST FOR EACH KIDNEY.

In healthy individuals the elimination of glucose by the two kidneys is equal and parallel. Variations in the work of the two organs occur, however, which may amount to from 10 to 20 per cent. I have observed a difference of 0.45 grammes between the amount eliminated by each kidney

(1.20 right and 1.65 left) in a healthy individual. Albarran gives the following results in four healthy individuals:—

Right kidney.				Left kidney.			
1.	0.88	gramme.	...	...	0.68	gramme.	...
2.	1.20	"	...	...	1.14	"	...
3.	1.66	"	...	...	1.21	"	...
4.	1.80	"	...	...	1.62	"	...

The elimination of sugar commences in a healthy kidney in the first half hour and most frequently the first appearance of it is observed in from 15 to 20 minutes after the injection. The kidneys commence simultaneously to eliminate the sugar and cease almost at the same time. Elimination continues about one and a half to two hours, but may be more prolonged.

When one kidney is diseased there may be complete absence of sugar on that side, while the sugar eliminated by its healthy neighbour may represent the share normally taken by one kidney, leaving a reduction of the total sugar in the mixed urines; the total amount may not be reduced, since the healthy kidney may eliminate a quantity equal to two kidneys, or the second kidney may eliminate a diminished quantity of sugar, so that the total sugar is much reduced. Usually the quantity of sugar is diminished on the diseased side and normal on the healthy side. Rarely a hyperglycosuria may be observed on the diseased side.

The following case may be referred to fully, for it has points of interest in diagnosis as well as in the estimation of the renal function.

The patient, aged 54 years, was admitted to St. Peter's Hospital under my senior colleague, Mr. P. J. Freyer. In his absence it fell to me to examine the bladder with the cystoscope and he kindly permitted me to make further observations upon the patient in regard to his renal function. There was a history of frequent micturition during the day and night for months and scalding during the act. There had been difficult micturition and a poor stream for six weeks but never hæmaturia. The kidneys were not tender or painful and neither kidney could be felt under deep anaesthesia. Tubercle bacilli were detected in the urine. Vesical spasm rendered cystoscopy difficult. The bladder showed general sub-acute cystitis; the opening of the right ureter was far out on the side wall of the bladder; a thickened inter-ureteral bar led up and into a tunnel which represented the opening ("dragged-out" ureter). Palpation of the kidney on this side produced a powerful tug on this

muscular ridge. I catheterised the right ureter, drained the bladder, and injected five milligrammes of phloridzin. No sugar appeared in the urine collected from the right ureter and the urea varied from 0.8 to 1.0 per cent. The urine from the left kidney contained 0.296 gramme of sugar and the urea varied from 2.4 to 2.6 per cent. (Fig. 19). Mr. Freyer cut upon the right kidney and removed a large kidney containing masses of caseous material and a thickened ureter.

FIG. 20.

Large calculus pyonephrosis. Diminished elimination of sugar on diseased side.

Phloridzin failed to produce glycosuria on one side while it appeared in much reduced quantity on the other in two cases, where there was apparently insufficient cause. In one, a case of right-sided moveable kidney, the supposed healthy kidney eliminated no sugar while the moveable kidney produced only 0.037 gramme. In another, a very nervous man with attacks of left-sided renal colic and a history of hæmaturia, the painful kidney eliminated 0.46 gramme of sugar and the supposed healthy kidney none at all.

FIG. 19.

Chart of work of each kidney in case of advanced tuberculosis of right kidney. Absence of sugar on diseased side. Sugar indicated by thick continuous line, urea by thin continuous line, and quantity of urine by dotted line.

FIG. 21.

Case of moveable kidney. Elimination of sugar greater on diseased side.

The quantity of sugar eliminated on the diseased side was diminished while that from the healthy kidney was normal in a case of pyonephrosis containing large masses of calculi (0.335 gramme and 1.623 gramme) (Fig. 20). On the other hand, the elimination on the diseased side in a case of movable kidney was greater than that on the healthy side (Fig. 21), and in a case of stone in the renal pelvis there was a striking increase in the percentage of sugar in the urine on the diseased side over that present on the healthy side (Fig. 22).—In another case of renal pelvic calculus of small

for a shorter period of time. Frequently it is over in a quarter of an hour, sometimes in half an hour.

Clinical value of the test.—As a means of demonstrating the diseased side the phloridzin test is frequently more delicate than other methods. The fallacies which attend its use have already been noted. It must detract from the value of the test that cases have been observed when a diseased kidney eliminated a full quantity of sugar and a healthy (or supposed healthy) kidney passed none at all. A disadvantage of the phloridzin method is that it is very sensitive to slight changes in the kidneys and an exaggerated idea of the extent of the disease may be obtained by studying the glycosuria produced. Larger doses than those in use are more accurate, for there is less probability of a total absence of the glycosuria in slight lesions (Albarran). The cases in which these fallacies occur are exceptional and in the majority of cases in which I have used this method the result has proved reliable when tested by other methods or by operation. The short duration of the glycosuria is an undoubted advantage where the comparative work of the kidney is in question. I have seldom required to prolong the examination beyond two hours in order to complete the phloridzin test. Where the phloridzin test is combined with an artificial polyuria it forms, I believe, a valuable method of estimating the function of each kidney.

Albarran's experimental polyuria test.—Albarran has established two general rules:—1. A diseased kidney has a much more uniform function than a healthy kidney and its function varies less from one moment to another the more its parenchyma is destroyed. 2. When one kidney alone is diseased or is the more diseased of the two, if the urinary function becomes disturbed it modifies its function less than the other, and the difference between the two glands is especially exaggerated by the variations in the function of the healthy kidney. If instead of examining comparatively the total quantity of urine secreted by each kidney during a certain space of time a series of fractions of the same time are compared the course of the function of each kidney may be studied. Curves may thus be constructed for comparison of the work of the kidneys, and according to Albarran the differences between the two kidneys may be accentuated in making them perform during the examination a supplementary labour, such as the elimination of water or of phloridzin glucose. Albarran estimates the quantity of urine, the Δ and ΔV , urea per litre and in centigrammes, the sugar per litre and in centigrammes. In the normal state the curves of the two urines follow each other and present similar variations (see Fig. 21). In pathological conditions the differences in the curve of each gland are readily observed. The sound kidney should show a reaction after drinking Evian water (Fig. 20). The curve of the quantity of urine should be elevated at the same time that the Δ is lowered and the urea and chlorides per litre are diminished. These oscillations should be evident and affect several divisions. One may consider satisfactory the elimination, by one kidney in an adult man, of from 1.20 grammes to 1.80 grammes of urea during the two hours of the test. Below 75 centigrammes to one gramme may be regarded as a fault of excretion. The ΔV presents as great variation as the quantity of urea. In a man one may look upon from 12,000 to 17,000 as good, from 8000 to 10,000 as mediocre, and 6000 and below as an impaired excretion.

FALLACIES OF METHODS OF ASCERTAINING THE RENAL FUNCTION.

Throughout these tests there run some fallacies that lie beyond the question of a perfect or imperfect technique. One factor is the partial activity of the kidneys in health. The renal function is not in full action at any one time and under ordinary conditions. If proof is wanted of this it is to be found in the fact that if the urines of the two kidneys are collected separately and compared it will be found that the kidney is working more actively than the other, while at another time the kidney, which was less active, is working with greater energy, yet over a sufficient

FIG. 22.

Calculus in left renal pelvis. Normal glycosuria. Percentage of sugar excessive on diseased side.

FIG. 23.

Calculus of left renal pelvis. Elimination of sugar practically equal on two sides.

size the elimination of sugar on the two sides was practically equal (Fig. 23).

Where sugar is eliminated at all by a diseased kidney the commencement of the glycosuria is frequently delayed beyond half an hour. It is usual when a diminished quantity of sugar is eliminated by a kidney for the glycosuria to last

period the work of the two will be approximately equal. The renal output under any ordinary conditions does not therefore correspond to the full potential function of the kidneys and the activity will increase where greater demands are made upon it. What the safety margin of renal tissue may be, apart from hypertrophic changes, it is difficult to say. Certain it is, from the removal of mechanically injured kidneys in the human being where no opportunity for hypertrophy of the second kidney has occurred that the safety margin amounts to half of the total renal tissue.

Mr. Henry Morris records a case⁸ which has an important bearing upon this subject. In a woman, aged 20 years, whose right kidney had been removed by another surgeon for tuberculous disease four years previously, he excised a tuberculous nodule involving about one-third of the left kidney. Seven years later this remaining portion of the kidney was explored and a quantity of pus was evacuated. The patient died four and a half months later from acute tuberculosis of the lungs. "Only two-thirds of one kidney existed and this remaining piece was very extensively fibrosed, so that the actual amount of secreting tissue must have been very small indeed." It appears, therefore, that the amount of renal tissue necessary for the secretion of an adequate quantity of urine is less than half the total quantity. The experiments of Dr. J. Rose Bradford⁹ on animals have shown that two-thirds of the total kidney tissue may be removed and the animal remain in good health, but if the quantity of kidney tissue be reduced to one-quarter death occurs after an interval. It is this margin of safety that introduces a fallacy into the methods of estimating the renal function. A kidney disease may operate within this and give no sign of its incursions upon the potential renal function until an operation such as nephrectomy reveals the fact that the patient has been living upon the minimum of kidney tissue and even a very slight reduction of this or a temporary interference with its action is sufficient to overturn the balance and to produce suppression of urine.

Although it is apparently beyond the range of practical surgery at the present time to estimate the potential renal activity, yet some approach to it might, I think, be made by the coincident use of diuretic drugs with the artificial means of estimating the renal function.

Further, we cannot foretell how far hypertrophy will compensate for the reduction of kidney tissue. Tuffier¹⁰ has studied this question by experiments on animals and concludes that compensatory hypertrophy only takes place when the kidney is partly or wholly normal. If it is the seat of parenchymatous nephritis the hypertrophy fails. According to this observer the quantity of renal parenchyma necessary for life is equal to about a quarter of the weight of the entire kidney tissue. A portion of kidney tissue equal to this weight suffices to reconstruct (by compensatory hypertrophy) a quantity of parenchyma equal in weight to one entire kidney.

Another factor is the difficulty in distinguishing between temporary functional depression and permanent reduction of function. To take an example, the obstruction of an enlarged prostate causes a reduced renal function that is partly temporary and partly permanent, the former being due to existing obstruction and the latter to interstitial changes in the kidney brought about by the obstruction. The removal of the obstruction will in such a case be followed by improvement in the renal function which it is impossible to measure beforehand. Yet upon this improvement the progress of the patient may depend after he has survived the removal of the obstruction.

Again, in the case of kidney disease the function of the second kidney may suffer depression partly from changes in its substance and partly, or perhaps wholly, from the reflex influences passing from its diseased neighbour. The removal of the diseased kidney or the source of irritation in it may be followed by a striking improvement in the function of a healthy or slightly diseased second kidney.

In these lectures I have endeavoured, in however hurried imperfect a manner, to place before you some of the problems which are now within the reach of the surgeon in attempting to estimate the function of the kidney in surgical cases of these organs. And at the outset I pointed out some of the points which might be set upon the estimation of the function. It is no part of this work to suggest that

the presence of renal disease should form a barrier to operation upon the lower urinary tract nor to surgical interference in the kidneys. The estimation of the renal function in surgical diseases has for its object the recognition of these cases which are hopeless from the permanent inadequacy of the renal function and their exclusion from operation.

In conclusion I would tender to the Council of the College my grateful thanks for the honour which it has conferred upon me in selecting me to deliver these lectures, thus enabling me to participate in the annual festival by which the College commemorates the name of John Hunter.

CARCINOMA MAMMÆ IN THE MOUSE.*

By E. F. BASHFORD, M.D. EDIN.,

GENERAL SUPERINTENDENT OF RESEARCH AND DIRECTOR OF THE
LABORATORY OF THE IMPERIAL CANCER RESEARCH FUND;

AND

J. A. MURRAY, M.B., B.Sc. EDIN.,

ASSISTANT, IMPERIAL CANCER RESEARCH FUND.

FROM the outset of the investigations of the Imperial Cancer Research Fund, in October, 1902, every effort has been made to give effect to the desire of the executive committee to develop the experimental aspects of the study of cancer. In directing the attention of other investigators to the experimental study of cancer we pointed out that, in the first place, it was essential to be sure we were dealing with malignant new growths comparable to those of the human subject.¹ We have carefully satisfied ourselves of the carcinomatous nature of the growths on which our experimental observations have been based, but have purposely avoided burdening our papers with details of descriptive pathology.² We have been equally careful in regard to sarcomata and have even excluded growths which other observers have claimed we should have included—e.g., certain venereal tumours of dogs. As regards the latter, we may say at once that we believe the course of events during the past four years has justified our caution. The high degree of natural infectivity, the constancy of the site of occurrence—viz., the genital organs—and the ease of artificial infection of healthy animals, as well as the processes responsible for infection showed that those tumours differ from other sarcomata which they resemble histologically. We concluded that the tumours were an infective venereal disease of dogs, perhaps comparable to syphilis of man,³ or better to granuloma pudendi. Stoker,⁴ Ewing and Beebe,⁵ and others, have opposed this conclusion, but Apolant⁶ in the most recent paper from Ehrlich's Institute acknowledges its correctness practically in our own words,⁷ even to adopting the analogy with syphilis.

In some of our earlier papers we have devoted great attention to the artificial reproduction of the natural lesions of cancer in mice⁸ owing to its importance as a starting-point for experiments. Detailed attention has been given to the nature of transplantation, to the interchangeability of expansive and infiltrative growth, and to extension by the blood-vessels and lymphatics; in short, to the reproduction of all the features of the primary or sporadic tumours. Although the evidence thus advanced must appear convincing to all who have studied it in unbiassed fashion, the experimental study of cancer has been subjected to much criticism, both at home and abroad. It seems necessary to meet this criticism in the frankest manner. At home some of it has been deliberately designed to inspire distrust in the experimental study of cancer, and particularly in that aspect of the work of the Imperial Cancer Research Fund, the only institution avowedly engaged in its pursuit in this country.

In the present paper are described certain anatomical and pathological features of sporadic tumours of the mouse. Detailed descriptions of a large number of similar tumours will be given by Bowen, Haaland, and ourselves in the Third Scientific Report now in course of preparation. The anatomical distribution of the tumours will be shown to correspond to that of the mamma. The histological differentiation they present will be referred to the normal histology of this organ in the mouse. The local infiltrative extension of the growths at their

* The superior figures occurring throughout the article refer to the bibliography at the end.

primary sites will be described. The formation of metastases by way of the blood and lymph streams will be clearly set forth. The evidence, added to what we have already published, leaves absolutely no reason to doubt that these tumours are epithelial new growths of the mouse, that they are malignant, and identical in nature with similar malignant new growths of the human subject. Therefore the results of experiments based on them must have direct importance with reference to the study of the disease in man, provided of course due caution be exercised when making comparisons between man on the one hand and the mouse on the other.

The development of the experimental study of cancer in the last four years has been achieved almost entirely as a result of the relative ease with which certain tumours of the mammary region of the mouse can be propagated artificially in normal animals of the same species. This line of inquiry has advanced rapidly. The new and interesting points of view opened up have engrossed those actively engaged in the work. They have proceeded to obtain new light on the nature of cancer, without engaging in the laborious task of convincing all and sundry of the soundness of the anatomical and histological basis of their investigations. The negative criticism to which experimental cancer research has been continuously subjected has repeatedly shifted its ground, while new facts coming to light have more and more fully justified confidence in experimental investigations.

The objections raised against regarding these tumours as mammary carcinomata are as various as the authors who have raised them; practically no two are agreed either on their actual features or on those of malignant growths in the human subject justifying the objections. They can be grouped in three classes. 1. The sporadic tumours in mice are stated to be not cancer at all. 2. The facts elicited in the course of their experimental propagation are stated to be so out of accord with clinical and pathological observations on the human subject as to have little or no value. We shall refer to the preceding objections in detail below. 3. The third class of objections can be summarily dismissed, since they are entirely misdirected. They pertain to matters of quite subsidiary importance, compared with the larger question of whether these tumours permit us to study any form of cancer experimentally. The resuscitation⁷ of the opinion of Eberth and Spude,⁸ now only maintained by Lazarus-Barlow, that such tumours are endotheliomata, is one example. Ribbert, while regarding them as epithelial tumours of the mamma, denies them malignancy⁹ in the sense that they present characters associating them with the malignant tumours of man, mainly, it would appear, because of the difficulties of harmonising the results of experiment with Ribbert's own hypothesis of the origin of cancer. Ribbert has overlooked the fact, that the transplantation of these growths affords the experimental demonstration of his contention, that malignant new growths grow from their own resources only. Others profess to see a quite usual phenomenon in the extraordinary powers of proliferation exhibited by a mouse tumour when artificially propagated,¹⁰ namely, "nothing more than a universal and long recognised capacity in cells." The normal tissues of a mouse, or any other vertebrate, are devoid of similar powers of proliferation. They present a contrast to cancer and cannot be transferred an infinite number of times from one animal to another with retention of undiminished powers of growth. Nor can the transplantation of cancer in the vertebrates be explained by an analogy with the propagation of the higher plants by means of grafts or cuttings. We have already considered this analogy, which so naturally suggests itself, and dismissed it.¹¹ Apart from its theoretical importance, the value of the artificial propagation of cancerous tissue rests on the fact that it affords opportunities for experimentally modifying the rate of cell growth and multiplication: in other words, for directly attacking that property of cancer by virtue of which it destroys human life.¹²

The objection that the tumours under discussion are not cancer can be dispelled by a knowledge of their pathology and of the normal anatomy and histology of the mouse's mamma in the immature condition, in rest, and in functional activity. The mamma in the mouse usually consists of five pairs of glands, occupying the sides and front of the body from the neck to the anus. In the shoulder region the gland-acini extend round the sides of the body in front of and behind the forelimbs, meeting dorsally in the middle line. In the inguinal region there is a similar extension along the crest of the ilium and on the inner

aspect of the thigh. The general distribution is shown in Fig. 1, in which the position of 42 spontaneous tumours is indicated also. In Figs. 5 and 6 the extensor level of the shoulder girdle is shown on the right side of the body, in transverse sections of a mouse.

FIG. 1.

a large carcinoma in the left axilla. It is evident that the tumours with which we are concerned correspond in their distribution to the normal mamma. The cervical region, the axilla, the nape of the neck, the inguinal region, and the vulva are all frequent sites. This distribution, as already pointed out by Apolant¹³ and ourselves, indicates the mamma as the tissue of origin. A fully developed gland in a state of rest (when the animal is not suckling), consists of delicate branching acini lined by cubical epithelium (Fig. 2) and lying in

FIG. 2.

Normal adult mamma. The mouse had born young but was not suckling. Shows variability of lining epithelium from cubical to flattened cells, according to the degree of distension of acini by secretion.

areolar and fatty tissue subjacent to the panniculus carnicus, which, in the mouse, forms an almost complete sheath to the body. During active secretion the acini become dilated and form branching sinuses. The lining epithelium frequently becomes stretched till it resembles a pavement epithelium or endothelium. Fig. 3 illustrates the gland characters of an adeno-carcinoma and that its relation to the panniculus carnicus corresponds to that of the mamma. The new-born female the gland is much less extensive, forming a few branching columns of cells in the vicinity of the nipples. The acini are usually solid, although lumina may be recognised in places. For the most part, the pos-

of the future lumen is merely indicated by the recession of the closely packed nuclei from the central part of the cellular strand (Fig. 4). Cell division is frequent at this period. The gland is growing rapidly. The cells are small, and it is often difficult to say whether an individual nucleus at the surface belongs to the gland parenchyma or to the connective tissue. The tumours first appear as roughly spherical swellings usually placed asymmetrically with reference to the nipple as in the human subject. The small

size of the mouse, and the looseness of its integuments often permit this shape to be retained till the increase in size is incompatible with existence, there being a limit to the amount of tissue which the animal can support. The looseness and elasticity of the skin may permit growth to proceed without invasion of the chest wall in tumours in the axillary region, although the lungs may be almost completely replaced by metastatic growths. Lymphatic glands in the neighbourhood may also present secondary deposits, as in Figs. 7, 9, and 11. These mammary growths frequently appear, on removal of the skin, to be encapsuled completely by a fibrous layer of varying thickness. This "capsule," however, is usually invaded by strands and columns of tumour cells, as in the accompanying figure (Fig. 8). The complete surgical

removal of the tumours can be effected only by removing the capsule and surrounding tissues and not by shelling the tumour out of its "capsule" after incision.

When a growth arises in the limited space between the thigh and the pelvic outlet it soon fills up all the available room and then its further extension takes place

in an infiltrative manner, as in the case represented in Figs. 9 and 10. The thigh on the affected side is seen to be twice as thick as that on the healthy side, due to the intercalation of the growth between the muscles. Fig 10 represents in silhouette the manner in which the growth penetrates between the muscles. The

muscle fibres disappear from between the alveoli of the tumour parenchyma, apparently by pressure atrophy; there is nothing to indicate a digestive action of the tumour on the surrounding structures any more than in the new growths of man. In this case there is also extensive infiltration of the connective tissue between the vagina and rectum. After death this mouse presented large metastases in the lungs

FIG. 8.

and, in addition, in the aortic lymphatic glands, as indicated in the section of the whole mouse (Fig. 9) and for a lymph gland alone, under a higher magnification, in Fig. 11. The asymmetrical position of the tumour nodule and the displacement of the lymphatic tissue to form a crescentic margin indicate that growth has commenced in the marginal sinus of the gland as in lymphatic metastasis in the human

FIG. 9.

subject. These illustrations show that we are dealing with new growths of the mammary region of the mouse, which grow freely fully (new after incomplete removal), infiltrate the surrounding normal tissues, and produce metastases of the same histological type in the lungs and lymphatic glands. They lead to the death of the animal. Its conclusion is inevitable that they are malignant new growths of the mamma.

We now approach the subsidiary question: Do tumours arise from the epithelium of the acini of the mammary gland (adenoma, carcinoma), from the endothelium of blood or lymph-vessels (endothelioma) or from the connective tissue (sarcoma)? There are no other possibilities. The third mode of origin may be discarded at once. The tumour is not sarcomatous. A conclusion as to the histogenesis of the tumour is a reasoned judgment based on a knowledge of histological differentiation of the tumour parenchyma of the normal tissue implicated, in the various stages of growth and functional activity. The actual connexion

FIG. 10.

Silhouette of margin of growth where invading the muscles of the thigh.

the tumour with its parent tissue is very rarely seen an conclusion is adopted which harmonises most naturally these two sets of facts—the normal histology, on the one hand, and the tumour histology on the other. Bearing in mind, it is easy to show that these mammary tumours of the mouse present a graduated series, from growths of small acini, indistinguishable from those of the resting mamma, through others, in which the acini dilated into cystic spaces, reproducing in an exaggerated form the puerperal condition, to alveolar growths, but

FIG. 11.

the plan of the rapidly growing mammary foundation of a new-born mouse. We do not regard this similar alveolar carcinoma as immature normal mamma as but a return to an embryonic condition, but merely as that an epithelium which will certainly differentiate into a mass of acini lined by one layer of cubical cells through a growth-form in which many layers of c

columns of cells predominate. Therefore the presence of similarly constituted alveoli in a tumour does not preclude that they have arisen from simple acini lined with one layer of cells. These tumours present us with every imaginable intermediate stage from pure adenoma to alveolar carcinoma, and our classification must recognise the continuity of this series of histological appearances. Adenomatous and solid alveolar portions are frequently encountered in the same growth. The situations in which they occur indicate clearly, in many instances, a mechanical influence as determining the histological appearances. The transplantability of many of these tumours gives further opportunities for determining the share of mechanical conditions in modifying the histology. With the development of this line of inquiry we shall soon see that, instead of attempting to classify mouse tumours in accordance with human histology, the results of experiment will force us to modify the rigidity of the classification now in vogue. The clinical, pathological, and cytological distinctions which even to-day it is sought to draw between benign and malignant growths break down entirely in the face of the facts revealed by the comparative and experimental study of cancer. It is becoming more and more certain that the explanation of growths in the one class will also elucidate the nature of those in the other.

Our knowledge of cancer in mice is by no means limited to carcinoma mammae as seems to be generally believed. We have described and figured an adeno-carcinoma of the duodenum,⁶ and a similar case has been described by Bulloch and Twort¹⁴ in which extensive secondary growths were present in the liver. We have also described a case in which the histological appearances were those of the pancreas.⁶ In yet another case Jensen found a large growth surrounding the kidney in a mouse which we had sent to him: it had the structure of a spindle-celled sarcoma. Haaland has described¹⁵ a number of malignant growths in mice observed in Borrel's laboratory, and we have already reproduced a figure¹⁶ of one of several cases of squamous-celled carcinoma of the floor of the mouth described by him. The carcinomatous ulcer in that case reproduced the appearances in the same site in the human subject very closely. The secondary growths in the marginal sinus of the submaxillary lymphatic gland are typical. The invasion and destruction of the ramus of the lower jaw complete the clinical and pathological picture in this most interesting case. Haaland has also published¹⁷ preliminary accounts of multiple enchondromata, of chondro-sarcoma, and of squamous epithelioma of the vulva. The typical features of the last case entirely dispose of the doubts expressed by Erdheim¹⁸ in regard to a similar growth. Haaland will describe these cases in more detail in a future communication. We cannot refrain from referring to Ehrlich's¹² important material, which includes not only very numerous mammary growths, but also chondroma and spindle-celled sarcoma. In the papers published by the many investigators who have large personal experience of cancer in mice there is not one discordant note. Michaelis has authorised us to state that he is wrongly quoted¹⁰ as holding that the growths in mice are not cancer.

The criticism that the facts elicited by the experimental study of cancer are out of accord with clinical and pathological observations on the human subject, has done duty repeatedly with reference to other diseases. It has been brought forward whenever the first fruits of experimental investigations have clashed with empirical conceptions—clinical or pathological. It is matter of history that it was used with effect on Villemin's early experiments on the infective nature of tubercle and applied also to Koch's monumental research in which he finally demonstrated the cause of the infection. The same battle had to be fought in the case of diphtheria. This form of criticism is to be welcomed, for on the whole it has a salutary influence, although its volume in the past has often been only an indication of the number of those who were unable to grasp novel conceptions or unwilling to appreciate their value.

It is not surprising that we should find this criticism applied to refer briefly to certain specific objections. It was pointed out over 40 years ago, on the basis of the results gained in the performance of 2000 necropsies at the Royal College of Surgeons, that "the cachectic condition spoken of in cancer is not present at all, and depends, as we have seen, upon accidental circumstances." Sir Samuel Wilks¹⁹ has applied equally to mice suffering from

cancer, either natural or induced. If we interpret recent surgical papers correctly, e.g., those by Mr. G. L. Cheate,²⁰ our opinions coincide with his in this matter. The spontaneous disappearance of tumours in the human subject in its relation to the similar phenomenon in mice after successful inoculation was first referred to by us in the course of a discussion at the Medical Society of London in March, 1905.²¹ At that meeting Mr. J. Langton and Mr. H. J. Waring recorded their personal experience of its occurrence and other surgeons have done so since. A most interesting case has been recorded quite recently by Mr. W. Bruce Clarke.²² With Cramer we have fully described the nature of the process in mice and pointed out its identity with what Orth²³ had described for epithelioma of the human tongue. In regard to mice with inoculated tumours, the importance of the phenomenon has also been emphasised independently by Clowes.²⁴ Clowes and Gaylord²⁵ tabulated the recorded cases in the human subject and confirmed our description and figures in the case of mice. Those objecting that its relative frequency shows cancer in mice is not comparable with cancer in man have entirely overlooked the fact of our statements referring to cancer when transplanted in normal animals rather than to sporadic growths in the animals spontaneously attacked. The great importance of this phenomenon cannot be denied. Its apparent novelty has, perhaps, much to do with the incredulity with which our statements have been received. In the human subject, in chorion epithelioma, spontaneous healing of the secondary growths presents the closest parallel to its occurrence in experimental cancer. In chorion epithelioma we have a form of cancer which is naturally transferred from one individual to another by transplantation—viz., from the cancerous chorion to the healthy mother. The frequency of the spontaneous healing of the secondary growths thus occurring in the mother is a matter of common knowledge among pathologists. Mr. Pearce Gould has drawn attention to spontaneous healing of cancer of the human breast and of the secondary nodules in melanotic sarcoma. Mr. W. S. Handley has emphasised the significance of the phenomenon. On the one hand, the human organism is able to protect itself against malignant growths, at least occasionally, and perhaps more frequently than we are yet aware of. On the other hand, mice inoculated with cancer are very frequently able so to protect themselves in certain favourable circumstances.

As regards statements which have been made about the frequency of infection in mice, we have discussed this subject so often that we can dismiss it by reiteration of the facts. We have taken every care to show how absolutely distinct from all known processes of infection is the artificial transference of the disease. The establishment of this distinction by Jensen²⁷ and by us^{1,2} is one of the salient results of the experimental study of cancer. We have observed the effects of inoculating 60,000 mice with carcinomata. The animals have been kept under painstaking observation. The development of tumours that could be referred to infection or contagion has been observed in not one single instance. Ehrlich¹² has performed a somewhat smaller number of inoculations but has employed a greater number of sporadic growths. His experience agrees with ours. The housing of mice suffering naturally from cancer with normal animals has yielded no evidence of infection or epidemics, although our observations have now been extended over a longer period than any previous investigation and much longer than a mouse lives. The spontaneous appearance of tumours in our own and other experiments is to be explained in an entirely different way. The positive statements made in regard to infection when small animals suffering from cancer are housed with normal animals can be referred with confidence to (1) fallacious observations; (2) erroneous deductions as we have already pointed out²⁸ (Moran,²⁹ Gaylord³⁰); and (3) unwarranted assertions by those without personal experience. In our experiments mice have developed cancer spontaneously, though not by infection. We shall have occasion to revert to this topic. We shall show also how large an allowance must be made when large numbers of small animals are kept under careful observation, since the relative number of cases of cancer developing then more nearly approximates to the absolute incidence of the disease in animals alive in the later adult and old-age periods of life. The very positive statements about infection in the case of mice are at present devoid of all scientific value.

We are unable to comprehend why there should be a feeling that there is something mutually exclusive in the

clinical, pathological, comparative, and experimental methods of investigating cancer. They are really complementary to one another and those who have studied the publications of the Imperial Cancer Research Fund must have perceived that every effort has been made to give each line of inquiry its due importance, and to coördinate them as the respective parts of one extensive investigation. The purely clinical and pathological aspects of cancer have received a large share of attention. The statistical investigations of the Imperial Cancer Research Fund are based on the most numerous and reliable clinical and pathological data yet tabulated. In certain investigations on the earliest stages of squamous-celled carcinoma of the tongue, the ripe clinical experience of Mr. H. T. Butlin was supplemented by experience of a different kind, gained in purely pathological and experimental studies on human and animal material, with most important clinical results.¹⁴

We beg leave to conclude that the comparative, the biological, and the experimental investigation of cancer is based not only on sound foundations, but that it is advancing our knowledge²¹ of the disease more rapidly than any other line of inquiry at the present time.

ON OPSONINS AND IMMUNITY.¹

By J. L. BUNCH, M.D., D.Sc. LOND., M.R.C.P. LOND.,

LATE RESEARCH SCHOLAR OF THE BRITISH MEDICAL ASSOCIATION
AND ASSISTANT PHYSICIAN TO THE GERMAN HOSPITAL.

(From the Pathological Laboratory, University College,
London.)

It has for long been a matter of uncertainty to which of the constituents of the blood its germicidal properties are due. That such properties exist is, of course, undoubted, and some of the earliest experiments on the subject showed that bacteria when injected into the blood stream rapidly disappear. It was shown later that defibrinated blood could destroy various kinds of micro-organisms, although after a time this same blood lost its germicidal properties and became an excellent medium on which the bacteria could grow. The germicidal powers of fresh blood must, of course, depend either on some substance contained in the serum or in the corpuscles, or on some actively destructive action of the latter. The white corpuscles, or phagocytes,

have been shown to possess the power of taking up and digesting bacteria, probably by the aid of some intracellular ferment, and the method of which I am speaking—the opsonic method—depends on our ability to estimate the relative capabilities of the phagocytes to take up bacteria (known as phagocytosis) when incubated with and acted on by different blood sera.

Phagocytes are either of the macrophage—i.e., fixed—variety, consisting of endothelial cells, some connective tissue cells, and some cells of the spleen pulp and bone marrow, or of the motile variety, which includes most of the polynuclear and mononuclear leucocytes. When micro-organisms are introduced into the body the phagocytes, both fixed and motile, seize upon the intruders and by means of their pseudopodia absorb them into their interior and digest them. Where the phagocytes are naturally absent or scanty, as in the anterior chamber of the eye and cornea, the invading micro-organisms stimulate the animal's protective mechanism to hurry forward an army of defending phagocytes of the motile kind which give immediate battle to the intruders. This attraction of the phagocytes is due to what is known as positive chemiotaxis, and is most marked in those cases where the natural immunity is greatest—indeed, the greater the natural immunity of the organism to infection the greater is the positive chemiotaxis. When the bacteria have been taken up into the phagocyte they are either digested by some ferment action or destroyed by some chemical poison possibly related to nucleic acid, but this action is not immediate and the bacteria are not instantly killed. This is shown by injecting into an animal phagocytes containing bacteria, and it is found that by doing this we can induce infection in the susceptible animal. If the bacteria are very virulent and the phagocytes are placed under disadvantageous conditions the bacteria may get the better of the phagocytes and kill them, or, if spores have been taken up by the phagocyte, these may develop within the phagocyte into bacteria and destroy the phagocyte.

The influx of these white corpuscles, or phagocytes, to an infected area means that the organism is resisting the invading forces which threaten disease. The phagocytes are aided in their struggle by poisonous substances circulating in the fluids of the body, secreted possibly by the white corpuscles, which act upon the bacteria in such a way as to prepare them for digestion by the phagocytes. These bacteriotropic substances, or opsonins, make ready or prepare the bacteria for the further action of the phagocytes. The word "opsonin" is derived from *ὀψωνίω*, meaning "I cater for." That opsonins have this action is proved by the following experiment of Wright and Douglas. Two tubes are incubated for a quarter of an hour at 37° C., the one containing three volumes of normal serum *plus* one volume of staphylococcus emulsion (previously heated to 75° C. and cooled), the other containing three volumes of serum which had been heated to 60° C. *plus* one volume of staphylococcus emulsion (previously heated to 75° C. and cooled). On removal from the incubator the first tube (containing normal serum) is heated to 60° C. and cooled. The contents of each tube are then added to three volumes of white blood corpuscles and the number of staphylococci taken up per phagocyte is counted. It is found that the number of staphylococci taken up in the second case is only one-seventh as compared to that taken up in the first case: in other words, the opsonin acts directly on the bacterium.

The opsonic index of a patient to any one micro-organism is simply the expression of the relative power of the patient's opsonins to influence the taking up of the micro-organism by phagocytes, as compared to that of a healthy individual. For instance, 50 phagocytes can when incubated with a tuberculous patient's serum take up 100 tubercle bacilli, while 50 of the same strain of phagocytes when incubated with the serum of a healthy person take up 150 bacilli in the same time. The patient's opsonic index is then the ratio of 100 to 150, or $\frac{2}{3}$, or 0.6.

The actual estimation of the opsonic index can only be carried out in a laboratory, but all that the physician in charge of a case has to do is to fill a specially prepared tube with blood and forward it to the bacteriologist and in 24 hours he can be advised what the patient's opsonic index is and what dose of vaccine should be administered. The method of estimation is as follows:—

(c) Two specimens of blood are obtained (by pricking the finger and allowing the blood to flow into a glass tube), one from the patient and one from a healthy person. These

¹ In part a lecture delivered at University College, London, on Feb. 25th, 1907.

tubes are sealed up by placing the ends of the tubes in a flame and the blood is allowed to clot, forming a clear layer of serum.

(b) 0.5 cubic centimetre of blood is drawn from the finger into a tube containing 10 cubic centimetres of sterile 1.5 per cent. sodium citrate solution and shaken up. Sodium citrate combines with the calcium salts of the freshly shed blood and prevents clotting. The tube is placed in the centrifugal machine for five minutes until the corpuscles have sunk to the bottom and the fluid is pipetted off. 10 cubic centimetres of normal saline solution are placed in the tube and the tube is shaken to wash the corpuscles and then replaced in the centrifugal machine for five minutes. This is repeated twice again and the fluid above the corpuscles is finally removed. A layer of white corpuscles free from serum is now available.

(c) An emulsion of the bacterium in salt solution (1.5 per cent.) is made by pouring the latter over a 24 hours' growth on agar and shaking. The fluid is removed and centrifuged until the right density of emulsion is obtained.

The two specimens of serum, the washed phagocytes and the emulsion of bacteria, are now ready for use and are labelled and placed in a rack or vessel containing wet sand. Two sterile capillary pipettes fitted with rubber nipples are marked at a distance of one centimetre from the end with a blue pencil, and into each are drawn up the following fluids. Into the first, equal volumes of healthy serum, washed blood cells, and bacterial emulsion. Into the second, equal volumes of patient's serum, washed blood cells, and bacterial emulsion. The contents of each pipette are thoroughly mixed and drawn up again into the respective pipettes. The two pipettes are sealed at the capillary ends and both are placed in an incubator at blood heat for 15 minutes. Of course, if the sera of more patients have to be examined at the same time similar pipettes, each containing one patient's serum, washed blood cells, and bacterial emulsion, are placed in the incubator also for 15 minutes and examined against the control. At the end of 15 minutes the two pipettes are taken out of the incubator; a blood film is prepared from each, stained by Leishman's method, and examined under a $\frac{1}{4}$ -inch oil immersion lens, using a mechanical stage. The number of bacteria contained in 50 polymorphonuclear cells is counted in each case, and since normal serum is taken as having an opsonic index of unity, the number of bacteria contained in 50 cells on the patient's slide, divided by the number in 50 cells on the control slide, gives the opsonic index of the patient.

Fallacies may, of course, occur in the hands of inexperienced workers, especially if the tubes be incubated for different periods, or the serum be heated, or the films imperfectly prepared, or the volumes incorrectly measured. But by practice a wonderful degree of accuracy can be attained.

Having determined the patient's opsonic index we have now to see whether we can raise it, if low, by the employment of bacterial vaccines. It is well known that many living organisms produce, during their growth, substances inimical to themselves. For instance, yeast grown on grape sugar produces alcohol, and this alcohol finally stops the growth of the yeast. Many bacteria in the same way produce during their growth substances (antibodies) which are injurious to themselves. Tuberculin contains such antibodies and is hence employed in tuberculous lesions, but in the old days much too large doses were employed and there was no method of checking its effects. Now, very small doses are given and we can tell with great accuracy what the results of each dose are. Nevertheless, tuberculin treatment must still be combined with other methods, and only under such conditions can bacterial vaccines be expected to give the best results.

The employment of sterilised bacterial cultures in the treatment of disease is based essentially on the assumption that by this means we can increase the germicidal substances of the fluids of the body and bring about a more or less marked artificial immunity. It is well known that immunity to snake poison can be induced by giving repeated small non-fatal doses of the toxin. 20 years ago it was shown that pigeons could by this means be made immune to the poison of the rattlesnake. This acquired immunity is, of course, to be distinguished from both natural and inherited immunity and may be either active or passive. Active immunity is brought about in the body of the animal as a result of the stimulus produced by the injection of bacterial cultures; passive immunity is the result of directly injecting

substances which can combine with and neutralise toxic bodies in the infected organism. Thus, in the case of diphtheria, active immunity can be produced in the horse by the injection of gradually increased doses of diphtheria toxin until its serum contains a considerable quantity of diphtheria antitoxin. This serum when injected into a patient suffering from diphtheria can neutralise a certain proportion of the toxin by virtue of the antitoxin which it contains, and so prevent some of the pathological changes in the patient's cells which would otherwise be brought about by the diphtheria toxin. By the injection of such antitoxin passive immunity is said to be produced in the patient.

Natural immunity to poisonous substances is possessed in various degrees by different animals. Thus large quantities of antimony and arsenic can be consumed by pigs without ill-effects, and the vapour of formalin, which is, of course, a strong antiseptic, is not only without effect on certain insects but they actually appear to thrive on it. Typhoid fever, so fatal to man, cannot be induced in the lower animals by inoculation with the typhoid bacillus, nor does the disease occur naturally in them, any more than do measles, scarlet fever, and leprosy. On the other hand, certain species of animals are susceptible to anthrax, such as sheep and cattle, whereas many other of the lower animals are quite insusceptible to the disease. But although some animals are immune to certain diseases and cannot be inoculated with the micro-organisms which produce these diseases, they are, nevertheless, susceptible to doses of the toxin produced by these micro-organisms and injection of typhoid toxin is fatal to many of the lower animals which cannot contract the disease. The toxin of cholera is harmless to the larva of a certain beetle, and if the same dose of cholera toxin is given to one of these and also to a small frog of equal weight the latter dies while the former is unaffected. If, however, the two are inoculated with the bacillus of cholera the frog escapes but the beetle dies. It is evident that this may apparently be explained on the assumption that the leucocytes of the beetle are able to get the better of the cholera toxin but not of the bacilli, and *vice versa* in the case of the frog, but what is not so easy to explain is why the beetle is unaffected by the cholera toxin introduced from outside, while it succumbs to that manufactured in its own body.

The mode of entry is often of the greatest importance in the future development of an invading organism. Thus the organism of Asiatic cholera is extremely fatal when taken into the alimentary canal, although it is almost harmless when injected subcutaneously. Tetanus bacilli and anthrax bacilli, however, when injected subcutaneously are very fatal, but if taken into the healthy alimentary canal they are practically harmless. The bacillus coli is normally found in the human intestinal canal and under such conditions produces no ill-effects because its toxic material is locked up inside the cell, but if the bacillus escapes into some position where by phagocytic or other action its intracellular toxin is set free pathological effects are speedily produced. The mode of entry of the tubercle bacillus and the nature of the bacillus which can cause tuberculous lesions in the human being are subjects which have been dealt with at length by the recent Royal Commission, and we are only concerned here with methods which can arrest the progress of disease in an already infected organism.

An increase of the opsonic content of the blood in disease is brought about by the injection of the appropriate vaccine—e.g., of tuberculin in tuberculosis, of staphylococci in boils and acne, and of gonococci in gonorrhoea. When possible the micro-organism should be grown directly from the patient's lesion and a small quantity of the pure culture, whether staphylococcus, tubercle bacillus, or other organism, triturated with normal saline solution to which $\frac{1}{4}$ per cent. lysol is added. The mixture is heated to 60°C. for an hour in order to kill the bacteria and make the vaccine sterile. The number of bacteria in a given volume is now calculated by mixing one volume with an equal volume of blood and two volumes salt solution and counting the relative number of bacteria and red corpuscles. It is known that normal blood contains about 5,000,000 red cells per cubic millimetre and the number of bacteria per cubic millimetre is therefore readily calculated and a vaccine of the required strength is easily prepared by dilution. An initial dose of 300,000,000 staphylococci, or $\frac{1}{10}$ milligramme of tuberculin, is given with a sterile hypodermic syringe subcutaneously. The injection should cause no rise of temperature and no general or appreciable local reaction. The amount of the dose given

at subsequent injections and the intervals between the doses must depend on the influence produced by the preceding dose on the opsonic index.

If the right dose has been given a short negative phase will be followed by a well-marked positive phase, during which the anti-bacterial power of the blood is increased and the resistance of the patient to the disease increased. After tubercle inoculations this improved power of resistance may be maintained for several weeks, but, as a rule, it falls back again after ten days or a fortnight, and a further dose of the vaccine is necessary. Only the minimal dose must be employed which will produce a satisfactory response and this must not be increased until it ceases to produce its effect. The dose, moreover, must not be repeated until the effect of the preceding dose is passing off. If it were possible to produce a summation of positive phases it would be advantageous to give successive doses at short intervals, so as to produce a maximal favourable effect, but such summation is not possible in the case of tubercle. Each inoculation, therefore, produces its effect independently and it remains to take the greatest advantage possible of the increased elaboration of protective substances which the artificial stimulus has produced.

The results of treatment of some dermatological cases have already appeared in a paper by Pernet and myself in the October, November, and December numbers for 1906 of the *British Journal of Dermatology*. Some cases were also included in a paper of mine in THE LANCET of Jan. 19th, 1907, p. 144. So many other successful cases have now been recorded that the employment of bacterial vaccines must in the future prove of the greatest service in the treatment of disease when controlled by the method which Wright and Douglas have so ably elaborated. In conclusion, I have much pleasure in thanking Professor Sidney H. C. Martin for his kindness, encouragement, and advice.

Park-street, Grosvenor-square, W.

A NOTE ON TESTS FOR ACETONE IN THE URINE.

By BASIL J. F. JACKSON TAYLOR, L.R.C.P. LOND.,
M.R.O.S. ENG.,

HOUSE PHYSICIAN, PADDINGTON GREEN CHILDREN'S HOSPITAL.

A FEW words on the tests for acetone in the urine may not be out of place at the present juncture when the conditions of recurrent vomiting with acetonuria are attracting so much attention. The tests ordinarily employed are: (1) the iodoform test; and (2) the sodium-nitroprusside test. The first mentioned is simple and, I believe, yields absolute evidence (with certain exceptions) together with microscopical examination of the iodoform crystals. The smell of iodoform produced when performing this test is unreliable, as a similar smell to that of iodoform is produced when iodine and alkaline solutions are added to urine irrespectively of the formation of iodoform. If acetone is present in small quantities distillation of the urine is advisable.

The sodium-nitroprusside test, which consists in the darkening which takes place on the addition of acetic acid to a solution of sodium-nitroprusside, urine, and liquor potassæ, is, I think, rendered more simple, delicate, and accurate by a slight modification—namely, the substitution of strong ammonia for the liquor potassæ and the elimination of the use of acetic acid. In the ordinary test when the solution of potash is employed there is a uniform reddening of the whole solution which on the addition of acetic acid in the presence of acetone becomes darker when the acid comes in contact with the urine, the darkening passing down as the acid sinks. Therefore, with this test the addition of liquor potassæ to the urine and sodium-nitroprusside yields a red colouration whether acetone is present or not, and it is only after the final addition of acetic acid that the presence of acetone is recognized and then only when there is a fair amount of the latter present. The detection of the presence of acetone is therefore dependent on the darkening of an already darkish red fluid by the final reagent acetic acid, and the degree of darkening, when acetone is present only in small quantities, is not altogether easy to determine. If, however, strong ammonia replace the potash solution the test for acetone is as follows. On adding the ammonia to a solution of sodium-nitroprusside and urine the ammonia solution remains on the

top; thus there is a clear solution uppermost with the urine solution below. Should acetone be present, even in minute quantity, a well-marked and absolutely characteristic ring of magenta (or petunia) appears within from one to three minutes at the junction of the two fluids and gradually spreads upwards pervading the whole of the ammonia solution if acetone is present in considerable amount. In the absence of acetone usually no colouration occurs, but sometimes an orange-red ring forms at the junction of the urine and ammonia solution, but this bears no resemblance to the "acetone ring" described above, hence the presence or absence of the latter is easily ascertained by the method which I believe has not been generally recognised.

The strength of the solution of sodium-nitroprusside is not important, but it is important that it should be prepared fresh and a few crystals dissolved in a test-tube of water are sufficient.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF RUPTURE OF A VERY EARLY EXTRA-UTERINE GESTATION; LAPAROTOMY; RECOVERY.

By O. A. SCOTT RIDOUT, M.S., M.B. LOND., F.R.C.S. ENG.,
SURGEON TO THE PORTSMOUTH AND SOUTH HAMPSHIRE AND
EAR INFIRMARY; HONORARY PATHOLOGIST TO THE
ROYAL PORTSMOUTH HOSPITAL.

THE following case is somewhat unusual owing to the early age of the extra-uterine conception and the entire absence of signs and symptoms preceding the rupture.

On Oct. 28th last I was asked by Dr. M. Aston Key of Southsea to see a young married woman in consultation who was presenting signs of some severe abdominal lesion. The patient was a healthy young woman, aged 23 years, who was married as recently as August 29th, 1906. Shortly after this date she had a regular menstruation period lasting for one week; at the end of September another regular period took place and on Oct. 22nd she again began to menstruate. This last period was rather shorter than usual and ended on the 26th. Otherwise she was in excellent health and attended a concert on the 27th. There had been no history of dyspepsia, hæmatemesis, or melæna. Early in the morning of the 28th on going downstairs she felt very faint and experienced severe pain in the hypogastrium rather to the right side; she revived and fainted again and this recurred several times during the morning. Vomiting occurred once in the afternoon and showed no peculiar characteristics. As she was getting much worse her medical attendant was summoned. When I saw the patient about 6.30 P.M. she was lying on her left side, moaning and in a very collapsed condition. Her skin was blanched; the pulse at the wrist was only feeble, flickering, and uncountable; the pupils were dilated; the abdomen was tumid, not distended, and below the umbilicus it was dull to percussion. She was anaesthetised with ether and an incision was made to the right of the linea alba through the right rectus abdominis muscle below the umbilicus. On opening the peritoneal cavity about two quarts of dark blood and clots escaped. The right Fallopian tube and ovary were normal, but in the region of the isthmus of the left tube there was a small swelling of the size of a hazel nut, from a small opening in which was presenting a small bunch of chorionic villi, which came away during handling and was unfortunately mislaid. The left Fallopian tube was then removed, considerable difficulty being experienced in securing all bleeding points on the uterine wall, some of which had to be included in passing the ligatures. The left ovary was normal. The lower half of the peritoneal cavity was then cleaned with absorbent pads and the wound was closed by peritoneal, muscular, and cutaneous sutures. The patient was in a profound state of collapse and so two pints of saline solution were infused into the right arm intravenously. She rallied soon after the operation, however, and made an uneventful recovery, being able to get up in three weeks' time.

The situation of the pregnancy in the isthmus of the Fallopian tube undoubtedly led to its early rupture. The

tumour, from its size and the smallness of the bunch of chorionic villi, could not have been of more than four weeks' growth.

As regards the diagnosis, the signs and symptoms presented by the patient undoubtedly pointed to internal hæmorrhage of an extensive character and this led me immediately to explore the region of the Fallopian tubes as being the most probable source of the hæmorrhage occurring thus suddenly in a young, healthy, rosy-cheeked woman, particularly as vomiting was a late and unimportant symptom and there was no hæmatemesis or melæna. The slight shortening of the last menstrual period was the only symptom at all indicative of any pregnancy and this one must own was a very slight one. Still, I consider it is always important to make very searching inquiries into the menstrual history and I think that this opinion is confirmed by this case.

Southsea.

NOTES OF A CASE OF STRANGULATED HERNIA ASSOCIATED WITH ACUTE HÆMORRHAGIC PANCREATITIS.

BY WALTER H. BROWN, F.R.C.S. IREL.

THE patient in the following case was a man, aged 60 years, and was admitted into the Leeds General Infirmary on August 2nd, 1903. The previous history was to the effect that he had enjoyed good health up to the day before admission, but on the evening of that day he was seized with a sudden and violent pain across the abdomen between the umbilicus and pubes. He vomited once or twice during the night. On admission the abdomen was somewhat distended and tender. There were a large hydrocele on the left side and a large hydrocele and hernia on the right side. The hernia was irreducible and tender. Shortly after admission he vomited a few ounces of dark fluid having a distinctly faecal odour. His general condition was extremely bad, his pulse was 130 per minute and very feeble, and he was obviously in great distress.

After ether had been administered the hernia was operated upon and was found to consist of a large coil of small intestine, deep purple in colour, but not strangulated completely. The bowel was returned without trouble and the pillars of the ring were sutured. The operation evidently had no material effect towards giving relief; he continued to vomit at intervals and died next day. It may be well to note here that flatus was passed several times after the operation, but none before it.

At the necropsy it was found that the scrotum contained a double hydrocele; behind the one on the right side there was an old hernial sac now empty; the inguinal canal was closed by suture. The lungs were much congested. The heart was normal. After opening the abdomen and removing the liver the parts in the neighbourhood of the lesser sac of the omentum gave way easily. The head of the pancreas was natural in size but very deep-coloured. On the upper aspect of the body of the pancreas there was a greyish slough of about the size of a walnut. The lesser sac was full of dirty curdy fluid resembling pus. The foramen of Winslow was closed. There was extensive fat necrosis of the great omentum and mesentery. The gall-bladder was full of small stones; the spleen was very soft; the kidneys were small and granular.

This was the first case of acute pancreatitis that I have had the opportunity of seeing post mortem. I observed at the time of the operation that the patient was far more ill than could be accounted for by his physical signs. The hernia, however, was irreducible and might, if gangrenous, be responsible for all the symptoms noted. After the operation I felt convinced that some intraperitoneal catastrophe had occurred but the patient's condition did not warrant further operative measures. Nor would any surgical procedure have afforded much chance of saving life, as, for instance, draining the lesser sac, fat necrosis being already present. Whilst it may be possible to diagnose pancreatitis in a given case observed during days of gradual onset I do not see how a surgeon is even to suggest its presence in an acute attack, more especially when the condition is associated with irreducible hernia. In the present case the disease was ushered in with no special symptom other than the familiar "sudden pain in body with vomiting," which symptom in scores of cases disappears and gives no further trouble. Alike from the patient's point of view and the surgeon's it is unfortunate that inflammation of the pancreas may occur without

previous warning of any kind, and may prove fatal in 48 hours without exhibiting any distinctive symptom, so that the nature of the illness is only discovered at the necropsy.

The pancreas physiologically is a peaceful organ, the pancreas pathological can be even as rapidly fatal in its attack, as the most virulent fulminating appendicitis.

PATHOLOGICAL SOCIETY OF LONDON.

Anti-typhoid Inoculation in the Army.—Observations on the Spirochæta of Relapsing Fever and Tick Fever.—A Note on Blackwater Fever in Sierra Leone.—A Pseudodiphtheria Bacillus from a case of Middle-ear Disease.—Bacillus Typhosus from Periosteal Abscess One Year after Typhoid Fever.

A LABORATORY meeting of this society was held at the Royal Army Medical College, Dr. P. H. PYE SMITH, the President, being in the chair.

Lieutenant-Colonel W. B. LEISHMAN, R.A.M.C., gave an account of the progress of Anti-typhoid Inoculation in the Army since the resumption of the method was authorised by the Army Council on the recommendation of the committee appointed by it to investigate the subject. The inoculations were voluntary but every effort was being made to popularise the method by means of lectures to all drafts and regiments proceeding on foreign service. As far as possible the inoculations were carried out before embarkation, but owing to various reasons the second inoculation was sometimes performed on board the transport. For this purpose vaccine was placed on board every outward-bound ship. The inoculations were also being carried out on a large scale in India and elsewhere and 20,000 doses of vaccine had been prepared and issued from the Royal Army Medical College during the last 12 months. Research work in connexion with the method had been carried on uninterruptedly at the Royal Army Medical College by Lieutenant-Colonel Leishman and his colleagues, Major Harrison, Major Grattan, and Lieutenant R. G. Archibald, and a short account was given of the lines of investigation and the practical bearing of some of the results upon the methods of preparing and standardising the vaccine. Numerous vaccines had been prepared from typhoid bacteria killed at different temperatures, by various chemical agents, by desiccation, &c., and their effects tested by measurement of the various protective substances which developed in the blood of inoculated animals. In several instances where the results appeared promising similar tests were carried out on man. The vaccine at present in use was described and an account was given of the mode of preparation and standardisation which had been somewhat modified from Sir A. E. Wright's methods in the light of the experimental work referred to. The bacteria were still killed by heat, but the temperature had been reduced to the minimum degree which would insure death in one hour—53° C. The deleterious effects of higher temperatures had been clearly brought out by some of the experimental work and it was suggested that the comparatively poor results obtained in some instances in the past might have been due to over-heating of the vaccine. The system adopted for ascertaining the protective value of the inoculations was then described, and the result of the inoculation of the 17th Lancers was given. This regiment, the only one which had been exposed to a severe epidemic of enteric fever since the modified vaccine had been in use, had 147 officers and men inoculated out of a strength of 509; they had 62 cases of enteric fever with 11 deaths; all of these occurred among the uninoculated with the exception of two, both being men who had refused the second inoculation; both of these men recovered.

Lieutenant-Colonel LEISHMAN, in a paper on the Spirochæta of Relapsing Fever and Tick Fever, after referring to the interesting nature of the problems awaiting solution in the connexion with many spirochæta infections, described the results of his own observations. His material consisted of films of blood from cases of African tick fever and of films of blood from Austria, Aden, and several parts of relapsing fever from Austria, Aden, and several parts of India; in addition, through the kindness of Professor Karl

Frankel he had had the opportunity of studying the living organisms of tick fever and of relapsing fever, the latter being the strain isolated in America and described by Ivy and Knapp. Lieutenant-Colonel Leishman had noticed the development of these organisms in white mice and, contrary to the usual experience, had found the strains equally fatal. The effect of passage appeared to be an undoubted increase in the virulence of the *Spirochæta* as evidenced by the earlier appearance of the organisms in the blood and their more rapid multiplication. It had failed entirely to confirm Novy and Knapp's description of easily recognisable morphological differences between a *Spirochæta* of tick fever, European relapsing fever, and *Diplo* relapsing fever, and had found wide variations in each case in respect of such features as length of the individual cell, number and depth of curves, tendency to formation of loops and figures of eight, &c. The inconstancy of these features appeared to him to depend upon such factors as the vitality of the organism, the stage of the disease, the method of fixation, &c. From other evidence, such as that of the immunity experiments of Breinl and Fraenkel and of Fraenkel, there appeared to be no doubt of a specific difference between the *Spirochæta* of tick fever (*Spirochæta Duttoni*) and relapsing fever (*Spirochæta Oberleineri*), but further work appeared necessary to prove the existence of two or more varieties of relapsing fever. As regards the biological nature of these *Spirochæta* which Novy and Knapp consider to be true bacteria Colonel Leishman pointed out that considerable differences of opinion and experience existed with respect to several of the points which these authorities considered as demonstrative of their bacterial nature. He had been unable to demonstrate flagella in either organism but had observed the structure which Haudin considered to be an undulating membrane in the *Spirochæta* of relapsing fever. A microscopical demonstration was given of the living organisms and stained specimens are shown of the different varieties both in human and in animal blood. The so-called undulating membrane was also shown in the case of a monkey *Spirochæta* and of *Spirochæta permerlei*.

Major H. W. GRATTAN, R.A.M.C., read a paper on Blackwater Fever in Sierra Leone. In eight out of ten cases malaria had been taken before the onset of "black water." Malarial parasites were present in the peripheral blood of 100 per cent. of cases after the onset of hæmoglobinuria. 100 per cent. of the cases harboured the *Ankylostomum* *moderate*. The red cells fell to 1,107,000 per cubic millimetre and the hæmoglobin to 25 per cent. in the most severe case that recovered. In two fatal cases 28 per cent. and 20 per cent. of hæmoglobin were noted. An absolute polynuclear leucocytosis was noted at the onset of the disease and later when suppression of urine occurred. 13,800 leucocytes per cubic millimetre was the highest count noted; this with 84 per cent. of polynuclears gave 11,592 polynuclears per cubic millimetre. No malarial parasites or pigment were found in the organs post mortem. It was considered that the evidence pointed to the disease being of malarial origin. His reasons were: (1) a previous history of malaria in every case; and (2) the presence of a malarial parasite in the blood of 38 per cent. of cases; and, further, he was of opinion that the disease was due to a special form of malarial parasite allied to, but distinct from, the parasite of malignant tertian. Specimens of blood films containing parasites were shown and charts illustrating the destruction and regeneration of the hæmoglobin and red cells.

Major W. S. HARRISON, R.A.M.C., showed a *Bacillus* resembling the *Diphtheria* *Bacillus* microscopically. It was isolated from an old case of chronic suppuration of the middle ear and was found in practically pure culture in the discharge. The organism stained by Gram, showed metachromatic granules when stained by Neisser's method, produced involution forms very like *Diphtheria* *Bacilli* in agar, and produced acid in broth. It differed from *Diphtheria* in its culture reactions, the growth on serum being thick and creamy, and on agar it gave a thick opaque yellow growth, the agar being gradually coloured brown and eventually becoming dark chocolate.

Major Harrison also showed a *Typhoid* *Bacillus* isolated from a sinus, following a post-typhoid abscess, a year after the attack of typhoid fever. It was extremely involutional, forming long strings similar to the cultures of *Typhoid* *Bacilli* on malachite green media; it gave, however, all the cultural characters of *Typhoid* *Bacilli* and was agglutinated by an anti-typhoid serum. The patient's

serum agglutinated other strains of typhoid bacilli in 1 in 200 to 1 in 400 and his own strain in 1 in 1000; the phagocytic ratio of the patient's serum was from two to four times greater than normal for other strains of typhoid bacilli and as much as 46 times greater than normal for his own strain, and his last high figure was probably accounted for by the fact that the bacillus isolated from the patient was very resistant to phagocytosis in mixtures containing normal serum only. Major Harrison found it difficult to account for the persistence of the organism in the body of a patient whose blood fluids showed such a high phagocytic ratio for typhoid bacilli.

LIVERPOOL MEDICAL INSTITUTION.

Nephrectomy for Renal Sarcoma in Children.—Plexiform Neuroma.—Variations in the "Normal Temperature."—A New Astigmometer.—The Surgery of Warfare and Catastrophe.

A MEETING of this society was held on March 14th, Mr. FRANK T. PAUL, the President, being in the chair.

Mr. K. W. MONSARRAT read a paper on two cases of Nephrectomy for Renal Sarcoma in Children with remarks on the Pathology and the Recent Results of Surgical Treatment. The first case was that of a boy, aged three years, the signs of disease being hæmaturia and abdominal tumour. The growth removed weighed 2 pounds 6 ounces. The child recovered from the operation but died from recurrence in six months. The growth was a sarcoma containing tubules and striated muscle fibres. The second case was that of a boy, aged five years, with abdominal tumour and hæmaturia. The child recovered from the operation and remained well at the end of six months. The growth weighed 2 pounds 2 ounces and was a pure round-celled sarcoma. Mr. Monsarrat found that published records indicated the occurrence of hæmaturia in about a third of the cases. He presented a statistical study of 104 cases published between the years 1897 and 1905 inclusive. These records showed that the present mortality from operation was 26 per cent. and that to the number of complete recoveries a total of seven had been added during the years examined. He considered that operation was justifiable in cases which showed no evidence of metastasis.—The President, Dr. N. PERCY MARSH, Mr. R. W. MURRAY, and Mr. A. STOKES discussed the paper.

Mr. G. G. HAMILTON showed a patient from whom he had removed a large Plexiform Neuroma. There were about 62 cases on record. In this case the tumour grew from the ilio-hypogastric nerve and was incorporated with the neighbouring muscle. It measured 10 inches by 4½ inches and showed numerous strands of nerve thickened to the size of a toothpick, many of them being coiled up into little capsules. There were very few axis cylinders present, the whole nerve being simply a mass of thickened gelatinous endoneurium. Mr. Hamilton's communication was illustrated by several lantern slides.—The pathology of the condition was discussed by Dr. E. E. GLYNN.

Dr. W. CARTER read a short note on Variations in the "Normal Temperature." After recalling the facts that Ogle and Liebermeister had recorded fluctuations varying from 1.8° to 2.3° F. in 24 hours and that Dr. Finlayson had observed that aged people in the Glasgow workhouse infirmary who died without any definite disease generally sank at the hour when in normal health the body temperature was lowest, he stated that on two occasions at distant intervals he had been able by the co-operation of the matron and night nurses of the Royal Southern Hospital to see if an inversion of the ordinary periods of night and day duty affected the normal rise and fall. Each nurse towards the end of her period of three months' night duty took her temperature three-hourly when not asleep in the day, but, as the charts, which were shown, proved, the normal depression which took place under ordinary conditions of life at about 3 A.M. remained fairly constant even after three months of turning night into day and vice versa. It seemed, therefore, to be deeply impressed on the organism and independent of external circumstances, so far, at least, as the trial of three months tended to establish the fact.

Dr. K. A. GROSSMANN explained the mechanism of his Astigmometer and demonstrated a working model.

Mr. ARTHUR J. EVANS in an interesting lecture on the Surgery of Warfare and Catastrophe, illustrated by

numerous lantern-slides from photographs and radiographs taken during the Boer War and after the earthquake in Jamaica, drew attention to the great contrast between the conditions under which surgery was practised in modern wars and those which obtained in sudden catastrophes such as an earthquake. In the one every contingency was attempted to be foreseen and provided for and the organisation was perfect beforehand; while, in the other, all aid had to be organised under the most appalling conditions and literally without a moment's notice.—The President proposed a vote of thanks to Mr. Evans for his lecture and of congratulation upon his escape from the earthquake and the great services which he had been able to render to the injured.—The vote was carried with very hearty cheers.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

The Prognosis and Treatment of Lobar Pneumonia.—Use of the Opsonin Index in the Diagnosis of Tuberculosis.

A MEETING of this society was held on March 6th, the chairman being at first Dr. BYRON BRANWELL and then Dr. J. O. AFLECK, the President.

The President communicated a paper entitled "Clinical Observations and Experiences in the Prognosis and Treatment of Lobar Pneumonia." If it were asked which of the acute diseases possessed the greatest interest for the physician, the answer would undoubtedly be, pneumonia. It could scarcely be answered satisfactorily as to the alleged increase in pneumonia as a disease as there were no direct means of determining its actual incidence in large communities. The Registrar-General's reports did not afford any definite information upon this point. The United States Census Reports for 1900 gave 106.1 deaths from pneumonia per 1000 deaths, against 90.6 in 1890 and 83.3 in 1880. More might be said on the question as to whether pneumonia had assumed a graver aspect of recent years. The President believed that this had been a more serious disease during the past 15 or 16 years than it had been previously. During the later "sixties" of last century his teachers did not regard pneumonia with the anxiety with which it was now the case and Hughes Bennett was wont to exhibit a list of over 100 uncomplicated cases without a death as due to his plan of treatment—viz., no drugs but feeding the patient. During the earlier years of the President's practice patients contracted the disease in a mild form and made good recoveries. When influenza appeared in 1890 pneumonia was one of the most serious of its complications. He felt sure that not a few cases of pneumonia were ushered in by influenza and thus the patient might suffer from the action of a double toxin. If this were so it would not be surprising that pneumonia should have assumed a severer form than was formerly the case. There was no means of foretelling at the beginning how the case would terminate and there were few diseases more treacherous in their liability to deviate from the normal course. In prognosis age was an important factor; excluding infants in whom the death-rate was very high, in the young and middle-aged uncomplicated cases might be expected to run a favourable course. In persons over 60 and especially over 70 years of age the mortality-rate was probably not less but more than 50 per cent. no matter what the previous health might have been. Habits, particularly the alcoholic, might outweigh the advantage of youth and vigor and might precipitate a fatal result. In the Royal Infirmary of Edinburgh in 1899-1900, of 19 cases of alcoholic pneumonia, 17 died; in 1900-01, of five alcoholic pneumonias, all died; in 1901-02, of 22 such cases, 18 died. Pneumonia occurring in the course of chronic maladies was of grave import, as it was also in acute infectious disease; where it followed surgical operations, though it might be grave, it was not always fatal. Pneumonia occurring during the acute forms of insanity was of grave prognosis. In some cases the patient might be overwhelmed by toxæmia from the first and might die in two or three days. Cases which exhibited prominent gastric and abdominal symptoms simulating some visceral lesion often turned out severe. Such cases had been mistaken for appendicitis. When pleuritic pain existed to any extent the prognosis was grave. Cases with copious perspiration and high temperature were serious from the great prostration. Nervous symptoms at the onset might

obscure the diagnosis. In drunkards delirium tremens might be one of the early accompaniments of pneumonia and it was a safe rule to take the temperature and to examine the lungs carefully in every case of alcoholic delirium, for death might occur with startling suddenness in such cases. In children convulsions might be the earliest sign of pneumonia, but did not necessarily imply an evil prognosis. The ability to sleep even for short periods was of the greatest importance. Marked and persistent insomnia was a grave symptom. Cases where no sleep could be induced even by hypnotics often ran an unfavourable course. Delirium to any considerable extent usually indicated an anxious case and it mattered not whether it was of the active or low typhoid form. The temperature did not furnish a trustworthy guide in prognosis. If it continued high (105° F.) with no remissions, the cases were grave. In the aged severe and dangerous types of pneumonia might be associated with low temperatures. The main determining factor in prognosis was the condition of the heart. There was reason to believe that the pneumonia toxin was both a heart and a lung poison. Profound toxæmia might be present while the area of lung involved was very small. The toxin affected both right and left heart equally. The lethal action of the pneumonia toxin on the vaso-motor centres might precipitate a sudden or gradual heart failure. The pulse rate and character were of the greatest importance in prognosis. In favourable cases in adults the pulse-rate seldom exceeded 120, even in the height of the disease. When it reached or exceeded 140 the patient seldom recovered. In none of its features was pneumonia more likely to exhibit its treacherous features than in the pulse. In the course of a few hours a case which had seemed to be going on favourably might become alarming in the extreme by the pulse becoming rapid and small. Such cases were usually fatal very soon after this change. At other times the lowering of blood pressure was slower but progressive and the prognosis was no better. These cases resembled the heart failures in diphtheria and were as resistant to treatment. In old people the rate was less important than the character, emptiness and irregularity being unfavourable signs. A moderate amount of expectoration was probably more favourable than none. Sputum was much less common in apical than in basal pneumonia; rusty sputum was better than bloody sputum. Cessation of expectoration with increasing cyanosis was very ominous. Double pneumonia was grave but almost equally so was complete consolidation of one lung. The President briefly described the chief characteristics of a favourable crisis and any non-conformity with these must be regarded with suspicion and anxiety. A rapid fall in the temperature with a continued rapid pulse, a rise in temperature when it should fall, or any symptoms of faintness or collapse, were of grave import. Sudden death from the mere exertion of sitting up in bed had often happened and therefore very little examination of the chest should be made. They had little power to arrest the progress of such a self-limited disease. The attempt to obtain early cure or abortion by means of sera had not as yet been encouraging. Attempts by depletion, &c., were of doubtful efficacy. The physician's work lay in guiding the case and in dealing with the symptoms which called for special treatment. The President's injunction to himself was, "Beware of meddling too much." The troublesome pleuritic pain might often be relieved by a hypodermic injection of from one-sixth to one-eighth of a grain of morphine. In hospital cases more than half of the patients stated that the application of the ice-bag to the painful side afforded relief; a certain number, however, could not bear it and wished it removed. It seemed most suitable in the young and vigorous and never seemed to have led to any increase in the pneumonic area. Warmth was, as a rule, well borne, but great heat was unnecessary and might aggravate the patient's discomfort. A moderately warm poultice often gave relief. The gamgee tissue jacket was all that was necessary in cases with no pain. Cough if troublesome often required treatment; dyspnoea was often of evil omen. The President's experience with oxygen inhalation had not been small but was disappointing. An ample supply of fresh air was always desirable. When the heart showed signs of failure digitalis, straphanthus, strychnine, and alcohol were useful remedies. Digitalis and strychnine were the most powerful in his hands and alcohol was inferior to strychnine as a stimulant. For insomnia paraldehyde given by the mouth or rectum was one of the best hypnotics. Opium in any form or dose he shrank from administering in the

advancing or advanced stage of a pneumonia. Dulcium might be treated by an ice-bag to the head and hyoscine was also useful. The pyrexia might be reduced by sponging such parts of the body as were easily reached but antipyretic drugs were not advisable from their heart-depressing tendency.—Dr. BRANWELL could never reconcile Hughes Bennett's results as he had always found the disease unassociated with a high mortality. He was certain that an antidotal serum would be found. He had seen cases of pneumonia mistaken for abdominal disease, as gastric ulcer, and even operated upon. He thought that jaundice in cases of right-sided pneumonia was very unfavourable. Dr. Branwell did not take so serious a view of a rapid pulse-rate (140) as the President. Irregularity of the pulse was of greater significance. Copious saffron-coloured sputum in influenza pneumonia was very grave. The expression of the patient was of great value in prognosis. Dr. Branwell prescribed very little alcohol, but thought that digitals, strychnine, and oxygen inhalations were of great value and he would wish to treat such patients by the open-air method.—Professor W. S. GREENFIELD said that in above 70 per cent. of cases vomiting at the onset was a feature. As regards treatment he had found that digitals often produced toxic symptoms and he had never seen any good results from strychnine and his only fatal cases had occurred under its use. It was in no sense a cardiac tonic. In all cases where the heart was failing he used atrophanthus. The ordinary tincture was useless and that of the pharmacopœia of 1835 had always to be prescribed. He employed five minims of this tincture with five minims of tincture of capsicum every three or four hours; then it might be increased to ten minims or even to 15 minims every half hour. Massive doses might be given even in apparently hopeless cases. Even in cases with a leucocyte count of from 3500 to 4000 improvement had resulted from such treatment.—Dr. ALEXANDER JAMES thought that the eruption of herpes was always a very favourable sign in prognosis. He was in the habit of giving a purge at the beginning of the disease and thought it valuable. He employed the ice-bag for the relief of the pleurisy and at the time of the crisis he found *mistura moschi* very helpful.—Dr. G. LOVELL GUILLAND said that the pneumococcus was found very often in the blood in fatal or in complicated cases. Leucocytosis was present in pneumonia, but in very severe cases there might be neither increase nor decrease, as might also happen in very mild cases. The case might be apparently going on well, but if the leucocyte count went on diminishing it was likely to prove fatal. The number of leucocytes should fall within one or two days after the crisis and if it did not then it pointed to serious symptoms. Cases where the eosinophiles persisted even in small amount were likely to do well.—Dr. WILLIAM RUSSELL said that the main factor in treatment was the maintenance of the heart's action. Strychnine acted on the vaso-motor centre and so improved the tone of the vessels. He appealed to Professor Greenfield to bring his experience and views more formally and fully before the society.—Dr. ALEXANDER GOODALL stated that he had been investigating the raw atrophanthus on the market for one of the manufacturing chemists and he had been surprised at the difference—some specimens had no more effect than so much water, while others were very potent and highly toxic.—Dr. W. E. CARNEGIE DICKSON and Professor H. HARVEY LITTLEJOHN took part in the discussion, and the PRESIDENT replied.

Dr. IAN STRUTHERS STEWART and Mr. L. O. PEEL RITCHIE communicated a Note on the Use of the Opsonic Index in the Diagnosis of Tuberculosis. In all forms of the disease early diagnosis was essential to successful treatment. Frequently, however, diagnosis was uncertain because of the indefiniteness of the early physical signs. The method which they submitted and at which they had been working for some time was one which rendered possible a diagnosis of tubercle even when the signs and symptoms were not conclusive. It consisted in the injection of a minute dose of tuberculin R. in conjunction with the observation of the tuberculo-opsonic index of the blood before and after inoculation. The conclusions were based on observations made on 122 consecutive cases of medical and surgical tuberculosis. The cases were divided as follows: 1. Those in which there was reasonable ground for diagnosing tuberculosis. In many diagnoses was based on pathological proof (examination of discharges, operation, &c.), and in the remainder by continued clinical observation. 2. Either normal cases or those suffering from diseases other than tuberculosis.

Several observers had shown that the tuberculo-opsonic index varied slightly in health. The normal limits of variation were from 0.8 to 1.2. The first group (tuberculosis) consisted of 83 cases. The indices of 41 fell within the normal limits and 41 outside. In the second group there were 40 non-tuberculous cases, of which 29 were within and 11 outside the normal limits. A diagnosis based on one examination of the tuberculo-opsonic index would have resulted in an error of diagnosis in one half the number. In the non-tuberculous cases 27.5 per cent. were outside the normal limits and a reliance on this test would have led to error to this extent. In acute tuberculous cases the swinging index might also lead to error in diagnosis. In a paper in conjunction with Dr. D. LAWSON of Banbury it had been shown that if a small quantity of tuberculin R. were injected into a tuberculous patient there was a diminution in the index but the reverse occurred in a healthy case. The method employed was as follows. The patient's blood was taken on the first day. Tuberculin was injected and the index estimated for the first and two succeeding days. The index of 1.0 was obtained from an examination of the blood of two healthy people. The bacilli ingested by at least 120 polymorphonuclear leucocytes were counted. The most suitable dose of tuberculin was 1/10th milligramme for adults and 1/20th milligramme for children. The depth of the negative phase was generally less where the primary index was low than where the primary index was high in an infected person. The usual fall in a tuberculous patient was 0.2. In 62 tuberculous patients inoculated a negative phase was observed in 56, or 90.3 per cent. In 13 cases (normal or non-tuberculous) a negative phase was not obtained after inoculation. The conclusions were: (1) the opsonic index *per se* was an unsatisfactory means of diagnosis, as both tuberculous and non-tuberculous cases fell within and without normal limits; (2) if a negative phase appeared after inoculation the existence of tuberculosis might be diagnosed; and (3) the absence of a negative phase indicated the absence of a tuberculous infection.—Dr. LAWSON (Banbury), Dr. GUILLAND, Mr. HAROLD J. SMITH, and Mr. BIRCHALL took part in the discussion which followed.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

Maniacal Chorea.—Moreable Spleen

A MEETING of the Section of Medicine was held on March 1st, Dr. JOSEPH M. REDMOND, the President of the section, being in the chair.

The PRESIDENT of the Academy (Dr. J. MAGEE FINNY) read a paper on Maniacal Chorea, basing it on the clinical report of a case which had lasted nine days from the onset of the chorea and which had been preceded by an attack of rheumatism of a fortnight's duration. The patient, a girl, aged 17 years, was admitted to Sir Patrick Dun's Hospital, Dublin, on June 14th, 1906, with chorea minor, and presented a distinct systolic apical murmur. This murmur was audible up to her death and was considered to be due to organic disease of the mitral valve. On the day following her admission the choreic movements became very violent. With the access of these movements maniacal symptoms set in and so greatly did they overshadow the motorial disturbance that the house surgeon believed the case to be one of acute mania. The temperature was not raised for five days, but on the sixth day it reached 103.4° F. for a few hours and the pulse-rate rose from 80 to 130 on the day of her death. Dr. Finny said that he never saw a human being so tossed about and agitated in every limb as this girl. The skin of her lips, back, arms, and legs was rubbed off from the violence and suddenness of the movements, as no appliances of wadding, bandages, and stockings could be kept on; and at times it required from four to eight persons to restrain her in bed. Calm was obtained—but very temporarily—by chloral, inhalation of chloroform, and the hypodermic administration of hyoscine hydrobromate in doses of 1/10th or 1/20th of a grain. Death was preceded by semi-coma of from six to eight hours' duration. All through the illness (except for the last day or two) intelligence was retained and she could occasionally answer a question in a few words. At the necropsy the brain showed very little gross alteration beyond engorgement of the vessels of the cortex and there was an absence of meningeal inflammation.

numerous lantern-slides from photographs and radiographs taken during the Boer War and after the earthquake in Jamaica, drew attention to the great contrast between the conditions under which surgery was practised in modern wars and those which obtained in sudden catastrophes such as an earthquake. In the one every contingency was attempted to be foreseen and provided for and the organisation was perfect beforehand; while, in the other, all aid had to be organised under the most appalling conditions and literally without a moment's notice.—The President proposed a vote of thanks to Mr. Evans for his lecture and of congratulation upon his escape from the earthquake and the great services which he had been able to render to the injured.—The vote was carried with very hearty cheers.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

The Prognosis and Treatment of Lobar Pneumonia.—Use of the Opsonin Index in the Diagnosis of Tuberculosis.

A MEETING of this society was held, on March 6th, the chairman being at first Dr. BYRON BRAMWELL and then Dr. J. O. AFFLECK, the President.

The President communicated a paper entitled "Clinical Observations and Experiences in the Prognosis and Treatment of Lobar Pneumonia." If it were asked which of the acute diseases possessed the greatest interest for the physician, the answer would undoubtedly be, pneumonia. It could scarcely be answered satisfactorily as to the alleged increase in pneumonia as a disease as there were no direct means of determining its actual incidence in large communities. The Registrar-General's reports did not afford any definite information upon this point. The United States Census Reports for 1900 gave 106.1 deaths from pneumonia per 1000 deaths, against 90.6 in 1890 and 83.3 in 1880. More might be said on the question as to whether pneumonia had assumed a graver aspect of recent years. The President believed that this had been a more serious disease during the past 15 or 16 years than it had been previously. During the later "sixties" of last century his teachers did not regard pneumonia with the anxiety with which it was now the case and Hughes Bennett was wont to exhibit a list of over 100 uncomplicated cases without a death as due to his plan of treatment—viz., no drugs but feeding the patient. During the earlier years of the President's practice patients contracted the disease in a mild form and made good recoveries. When influenza appeared in 1890 pneumonia was one of the most serious of its complications. He felt sure that not a few cases of pneumonia were ushered in by influenza and thus the patient might suffer from the action of a double toxin. If this were so it would not be surprising that pneumonia should have assumed a severer form than was formerly the case. There was no means of foretelling at the beginning how the case would terminate and there were few diseases more treacherous in their liability to deviate from the normal course. In prognosis age was an important factor; excluding infants in whom the death-rate was very high, in the young and middle-aged uncomplicated cases might be expected to run a favourable course. In persons over 60 and especially over 70 years of age the mortality-rate was probably not less but more than 50 per cent. no matter what the previous health might have been. Habits, particularly the alcoholic, might outweigh the advantage of youth and vigor and might precipitate a fatal result. In the Royal Infirmary of Edinburgh in 1899-1900, of 19 cases of alcoholic pneumonia, 17 died; in 1900-01, of five alcoholic pneumonias, all died; in 1901-02, of 23 such cases, 18 died. Pneumonia occurring in the course of chronic maladies was of grave import, as it was also in acute infectious disease; where it followed surgical operations, though it might be grave, it was not always fatal. Pneumonia occurring during the acute forms of insanity was of grave prognosis. In some cases the patient might be overwhelmed by toxæmia from the first and might die in two or three days. Cases which exhibited prominent gastric and abdominal symptoms simulating some visceral lesion often turned out severe. Such cases had been mistaken for appendicitis. When pleuritic pain existed to any extent the prognosis was grave. Cases with copious perspiration and high temperature were serious from the great prostration. Nervous symptoms at the onset might

obscure the diagnosis. In drunkards delirium tremens might be one of the early accompaniments of pneumonia and it was a safe rule to take the temperature and to examine the lungs carefully in every case of alcoholic delirium, for death might occur with startling suddenness in such cases. In children convulsions might be the earliest sign of pneumonia, but did not necessarily imply an evil prognosis. The ability to sleep even for short periods was of the greatest importance. Marked and persistent insomnia was a grave symptom. Cases where no sleep could be induced even by hypnotics often ran an unfavourable course. Delirium to any considerable extent usually indicated an anxious case and it mattered not whether it was of the active or low typhoid form. The temperature did not furnish a trustworthy guide in prognosis. If it continued high (105° F.) with no remissions, the cases were grave. In the aged severe and dangerous types of pneumonia might be associated with low temperatures. The main determining factor in prognosis was the condition of the heart. There was reason to believe that the pneumonia toxin was both a heart and a lung poison. Profound toxæmia might be present while the area of lung involved was very small. The toxin affected both right and left heart equally. The lethal action of the pneumonia toxin on the vaso-motor centres might precipitate a sudden or gradual heart failure. The pulse rate and character were of the greatest importance in prognosis. In favourable cases in adults the pulse-rate seldom exceeded 120, even in the height of the disease. When it reached or exceeded 140 the patient seldom recovered. In none of its features was pneumonia more likely to exhibit its treacherous features than in the pulse. In the course of a few hours a case which had seemed to be going on favourably might become alarming in the extreme by the pulse becoming rapid and small. Such cases were usually fatal very soon after this change. At other times the lowering of blood pressure was slower but progressive and the prognosis was no better. These cases resembled the heart failures in diphtheria and were as resistant to treatment. In old people the rate was less important than the character, emptiness and irregularity being unfavourable signs. A moderate amount of expectoration was probably more favourable than none. Sputum was much less common in apical than in basal pneumonia; rusty sputum was better than bloody sputum. Cessation of expectoration with increasing cyanosis was very ominous. Double pneumonia was grave but almost equally so was complete consolidation of one lung. The President briefly described the chief characteristics of a favourable crisis and any non-conformity with these must be regarded with suspicion and anxiety. A rapid fall in the temperature with a continued rapid pulse, a rise in temperature when it should fall, or any symptoms of faintness or collapse, were of grave import. Sudden death from the mere exertion of sitting up in bed had often happened and therefore very little examination of the chest should be made. They had little power to arrest the progress of such a self-limited disease. The attempt to obtain early cure or abortion by means of sera had not as yet been encouraging. Attempts by depletion, &c., were of doubtful efficacy. The physician's work lay in guiding the case and in dealing with the symptoms which called for special treatment. The President's injunction to himself was, "Beware of meddling too much." The troublesome pleuritic pain might often be relieved by a hypodermic injection of from one-sixth to one-eighth of a grain of morphia. In hospital cases more than half of the patients stated that the application of the ice-bag to the painful side afforded relief; a certain number, however, could not bear it and wished it removed. It seemed most suitable in the young and vigorous and never seemed to have led to any increase in the pneumonic area. Warmth was, as a rule, well borne, but great heat was unnecessary and might aggravate the patient's discomfort. A moderately warm poultice often gave relief. The gamgee tissue jacket was all that was necessary in cases with no pain. Cough if troublesome often required treatment; dyspnoea was often of evil omen. The President's experience with oxygen inhalation had not been small but was disappointing. An ample supply of fresh air was always desirable. When the heart showed signs of failure digitalis, straphanthus, strychnine, and alcohol were useful remedies. Digitalis and strychnine were the most powerful in his hands and alcohol was inferior to strychnine as a stimulant. For insomnia paraldehyde given by the mouth or rectum was one of the best hypnotics. Opium in any form or dose he shrank from administering in the

advancing or advanced stage of a pneumonia. Delirium might be treated by an ice-bag to the head and hyoscin was also useful. The pyrexia might be reduced by sponging; such parts of the body as were easily reached but antipyretic drugs were not advisable from their heart-depressing tendency.—Dr. BRANNWELL could never reconcile Hughes Bennett's results as he had always found the disease associated with a high mortality. He was certain that an antidotal serum would be found. He had seen cases of pneumonia mistaken for abdominal disease, as gastric ulcer, and even operated upon. He thought that jaundice in cases of right-sided pneumonia was very unfavourable. Dr. Brannwell did not take so serious a view of a rapid pulse-rate (140) as the President. Irregularity of the pulse was of greater significance. Copious saffron-coloured sputum in influenza pneumonia was very grave. The expiration of the patient was of great value in prognosis. Dr. Brannwell prescribed very little alcohol, but thought that digitalis, strychnine, and oxygen inhalations were of great value and he would wish to treat such patients by the open air method.—Professor W. S. GREENFIELD said that in above 70 per cent. of cases vomiting at the onset was a feature. As regards treatment he had found that digitalis often produced toxic symptoms and he had never seen any good results from strychnine and his only fatal cases had occurred under its use. It was in no sense a cardiac tonic. In all cases where the heart was failing he used atropine. The ordinary tincture was useless and that of the pharmacopœia of 1835 had always to be prescribed. He employed five minims of this tincture with five minims of tincture of capsicum every three or four hours; then it might be increased to ten minims or even to 15 minims every half hour. Massive doses might be given even in apparently hopeless cases. Even in cases with a leucocyte count of from 3500 to 4500 improvement had resulted from such treatment.—Dr. ALEXANDER JAMES thought that the eruption of herpes was always a very favourable sign in prognosis. He was in the habit of giving a piece of the lightning of the disease and thought it valuable. He employed the ice-bag for the relief of the pleurisy and at the time of the crisis he found *mistura moschi* very helpful.—Dr. G. LOVELL GULLAND said that the pneumococcus was found very often in the blood in fatal or in complicated cases. Leucocytosis was present in pneumonia, but in very severe cases there might be neither increase nor decrease, as might also happen in very mild cases. The case might be apparently going on well, but if the leucocyte count went on diminishing it was likely to prove fatal. The number of leucocytes should fall within one or two days after the crisis and if it did not then it pointed to serious symptoms. Cases where the eosinophiles persisted even in small amount were likely to do well.—Dr. WILLIAM RUSSELL said that the main factor in treatment was the maintenance of the heart's action. Strychnine acted on the vaso-motor centre and so improved the tone of the vessels. He appealed to Professor Greenfield to bring his experience and views more formally and fully before the society.—Dr. ALEXANDER GOODALL stated that he had been investigating the raw *strophanthus* on the market for one of the manufacturing chemists and he had been surprised at the difference—some specimens had no more effect than so much water, while others were very potent and highly toxic.—Dr. W. E. CARNEGIE DICKSON and Professor H. HARVEY LITTLEJOHN took part in the discussion, and the President replied.

Dr. IAN STRUTHERS STEWART and Mr. L. O. PEEL RITCHIE communicated a Note on the Use of the Opsonic Index in the Diagnosis of Tuberculosis. In all forms of the disease early diagnosis was essential to successful treatment. Frequently, however, diagnosis was uncertain because of the indefiniteness of the early physical signs. The method which they submitted and at which they had been working for some time was one which rendered possible a diagnosis of tubercle even when the signs and symptoms were not conclusive. It consisted in the injection of a minute dose of tuberculin R. in conjunction with the observation of the tuberculo-opsonic index of the blood before and after inoculation. The conclusions were based on observations made on 122 consecutive cases of medical and surgical tuberculosis. The cases were divided as follows. 1. Those in which there was reasonable ground for diagnosing tuberculosis. In many diagnosis was based on pathological proof (examination of discharges, operation, &c.), and in the remainder by continued clinical observation. 2. Either normal cases or those suffering from diseases other than tuberculosis.

several observers had shown that the tuberculo-opsonic index varied slightly in health. The normal limits of variation were from 0.8 to 1.2. The first group (tuberculosis) consisted of 82 cases. The indices of 41 fell within the normal limits and 41 outside. In the second group there were 40 non-tuberculous cases, of which 29 were within and 11 outside the normal limits. A diagnosis based on one examination of the tuberculo-opsonic index would have resulted in an error of diagnosis in one half the number. In the non-tuberculous cases 27.5 per cent. were outside the normal limits and a reliance on this test would have led to error to this extent. In acute tuberculosis cases the swinging index was also liable to error in diagnosis. In a paper in conjunction with Dr. D. LAWSON of Barchory it had been shown that a small quantity of tuberculin R. were injected into a tuberculous patient there was a diminution in the index but the reverse occurred in a healthy case. The method employed was as follows. The patient's blood was taken on the first day. Tuberculin was injected and the index estimated for the first and the succeeding days. The index of 1.0 was obtained from an examination of the blood of two healthy people. The bacilli ingested by at least 120 polymorphonuclear leucocytes were counted. The most suitable dose of tuberculin was $\frac{1}{10}$ th milligramme for adults and $\frac{1}{20}$ th milligramme for children. The depth of the negative phase was generally less where the primary index was low than where the primary index was high in an infected person. The usual fall in a tuberculous patient was 0.2. In 62 tuberculous patients inoculated a negative phase was observed in 56, or 90.3 per cent. In 13 cases (normal or non-tuberculous) a negative phase was not obtained after inoculation. The conclusions were (1) the opsonic index *per se* was an unsatisfactory means of diagnosis, as both tuberculous and non-tuberculous cases fell within and without normal limits; (2) if a negative phase appeared after inoculation the existence of tuberculosis might be diagnosed, and (3) the absence of a negative phase indicated the at once of a tuberculous infection.—Dr. LAWSON (Barchory), Dr. GULLAND, Mr. HAROLD J. STILES, and Mr. RITCHIE took part in the discussion which followed.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

Maniac Chorea—Mortable Spleen

A MEETING of the Section of Medicine was held on March 1st, Dr. JOSEPH M. RUDMOND, the President of the section, being in the chair.

The PRESIDENT of the Academy (Dr. J. MURPHY FINNY) read a paper on Maniac Chorea, basing it on the clinical report of a case which had lasted nine days from the onset of the chorea and which had been preceded by an attack of rheumatism of a fortnight's duration. The patient a girl, aged 17 years, was admitted to Sir Patrick Dun's Hospital, Dublin, on June 14th, 1906, with chorea minor, and presented a distinct systolic apical murmur. This murmur was audible up to her death and was considered to be due to organic disease of the mitral valve. On the day following her admission the choreic movements became very violent. With the access of these movements maniacal symptoms set in and so greatly did they overshadow the motor disturbance that the house-surgeon believed the case to be one of acute mania. The temperature was not raised for five days, but on the sixth day it reached 103.4° F. for a few hours and the pulse rate rose from 80 to 120 on the day of her death. Dr. Finny said that he never saw a human being so tossed about and agitated in every limb as this girl. The skin of her lips, back, arms, and legs was rubbed off from the violence and suddenness of the movements, as no appliances of wadding, bandages, and stockings could be kept on; and at times it required from four to eight persons to restrain her in bed. Calm was obtained—but very temporarily—by chloral, inhalation of chloroform, and the hypodermic administration of hyoscin hydrobromate in doses of $\frac{1}{10}$ th or $\frac{1}{20}$ th of a grain. Death was preceded by semi-coma of from six to eight hours' duration. All through the illness (except for the last day or two) intelligence was retained and she could occasionally answer a question in a few words. At the necropsy the brain showed very little gross alteration beyond engorgement of the vessels of the cortex and there was an absence of meningeal inflammation.

numerous lantern-slides from photographs and radiographs taken during the Boer War and after the earthquake in Jamaica, drew attention to the great contrast between the conditions under which surgery was practised in modern wars and those which obtained in sudden catastrophes such as an earthquake. In the one every contingency was attempted to be foreseen and provided for and the organisation was perfect beforehand; while, in the other, all aid had to be organised under the most appalling conditions and literally without a moment's notice.—The PRESIDENT proposed a vote of thanks to Mr. Evans for his lecture and of congratulation upon his escape from the earthquake and the great services which he had been able to render to the injured.—The vote was carried with very hearty cheers.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

The Prognosis and Treatment of Lobar Pneumonia.—Use of the Opsonin Index in the Diagnosis of Tuberculosis.

A MEETING of this society was held on March 6th, the chairman being at first Dr. BYRON BRAMWELL and then Dr. J. O. AFFLECK, the President.

The PRESIDENT communicated a paper entitled "Clinical Observations and Experiences in the Prognosis and Treatment of Lobar Pneumonia." If it were asked which of the acute diseases possessed the greatest interest for the physician, the answer would undoubtedly be, pneumonia. It could scarcely be answered satisfactorily as to the alleged increase in pneumonia as a disease as there were no direct means of determining its actual incidence in large communities. The Registrar-General's reports did not afford any definite information upon this point. The United States Census Reports for 1900 gave 108.1 deaths from pneumonia per 1000 deaths, against 90.6 in 1890 and 83.3 in 1880. More might be said on the question as to whether pneumonia had assumed a graver aspect of recent years. The President believed that this had been a more serious disease during the past 15 or 16 years than it had been previously. During the later "sixties" of last century his teachers did not regard pneumonia with the anxiety with which it was now the case and Hughes Bennett was wont to exhibit a list of over 100 uncomplicated cases without a death as due to his plan of treatment—viz., no drugs but feeding the patient. During the earlier years of the President's practice patients contracted the disease in a mild form and made good recoveries. When influenza appeared in 1890 pneumonia was one of the most serious of its complications. He felt sure that not a few cases of pneumonia were ushered in by influenza and thus the patient might suffer from the action of a double toxin. If this were so it would not be surprising that pneumonia should have assumed a severer form than was formerly the case. There was no means of foretelling at the beginning how the case would terminate and there were few diseases more treacherous in their liability to deviate from the normal course. In prognosis age was an important factor; excluding infants in whom the death-rate was very high, in the young and middle-aged uncomplicated cases might be expected to run a favourable course. In persons over 60 and especially over 70 years of age the mortality-rate was probably not less but more than 50 per cent. no matter what the previous health might have been. Habits, particularly the alcoholic, might outweigh the advantage of youth and vigor and might precipitate a fatal result. In the Royal Infirmary of Edinburgh in 1899-1900, of 19 cases of alcoholic pneumonia, 17 died; in 1900-01, of five alcoholic pneumonias, all died; in 1901-02, of 22 such cases, 18 died. Pneumonia occurring in the course of chronic maladies was of grave import, as it was also in acute infectious disease; where it followed surgical operations, though it might be grave, it was not always fatal. Pneumonia occurring during the acute forms of insanity was of grave prognosis. In some cases the patient might be overwhelmed by toxæmia from the first and might die in two or three days. Cases which exhibited prominent gastric and abdominal symptoms simulating some visceral lesion often turned out severe. Such cases had been mistaken for appendicitis. When pleuritic pain existed to any extent the prognosis was grave. Cases with copious perspiration and high temperature were serious from the great prostration. Nervous symptoms at the onset might

obscure the diagnosis. In drunkards delirium tremens might be one of the early accompaniments of pneumonia and it was a safe rule to take the temperature and to examine the lungs carefully in every case of alcoholic delirium, for death might occur with startling suddenness in such cases. In children convulsions might be the earliest sign of pneumonia, but did not necessarily imply an evil prognosis. The ability to sleep even for short periods was of the greatest importance. Marked and persistent insomnia was a grave symptom. Cases where no sleep could be induced even by hypnotics often ran an unfavourable course. Delirium to any considerable extent usually indicated an anxious case and it mattered not whether it was of the active or low typhoid form. The temperature did not furnish a trustworthy guide in prognosis. If it continued high (105° F.) with no remissions, the cases were grave. In the aged severe and dangerous types of pneumonia might be associated with low temperatures. The main determining factor in prognosis was the condition of the heart. There was reason to believe that the pneumonia toxin was both a heart and a lung poison. Profound toxæmia might be present while the area of lung involved was very small. The toxin affected both right and left heart equally. The lethal action of the pneumonia toxin on the vaso-motor centres might precipitate a sudden or gradual heart failure. The pulse rate and character were of the greatest importance in prognosis. In favourable cases in adults the pulse-rate seldom exceeded 120, even in the height of the disease. When it reached or exceeded 140 the patient seldom recovered. In none of its features was pneumonia more likely to exhibit its treacherous features than in the pulse. In the course of a few hours a case which had seemed to be going on favourably might become alarming in the extreme by the pulse becoming rapid and small. Such cases were usually fatal very soon after this change. At other times the lowering of blood pressure was slower but progressive and the prognosis was no better. These cases resembled the heart failures in diphtheria and were as resistant to treatment. In old people the rate was less important than the character, emptiness and irregularity being unfavourable signs. A moderate amount of expectoration was probably more favourable than none. Sputum was much less common in apical than in basal pneumonia; rusty sputum was better than bloody sputum. Cessation of expectoration with increasing cyanosis was very ominous. Double pneumonia was grave but almost equally so was complete consolidation of one lung. The President briefly described the chief characteristics of a favourable crisis and any non-conformity with these must be regarded with suspicion and anxiety. A rapid fall in the temperature with a continued rapid pulse, a rise in temperature when it should fall, or any symptoms of faintness or collapse, were of grave import. Sudden death from the mere exertion of sitting up in bed had often happened and therefore very little examination of the chest should be made. They had little power to arrest the progress of such a self-limited disease. The attempt to obtain early cure or abortion by means of sera had not as yet been encouraging. Attempts by depletion, &c., were of doubtful efficacy. The physician's prompt lay in guiding the case and in dealing with the symptoms which called for special treatment. The President's injunction to himself was, "Beware of meddling too much." The troublesome pleuritic pain might often be relieved by a hypodermic injection of from one-sixth to one-eighth of the grain of morphine. In hospital cases more than half of the patients stated that the application of the ice-bag to the painful side afforded relief; a certain number, however, could not bear it and wished it removed. It seemed most suitable in the young and vigorous and never seemed to have led to any increase in the pneumonic area. Warmth was, as a rule, well borne, but great heat was unnecessary and might aggravate the patient's discomfort. A moderately warm poultice often gave relief. The gamgee tissue jacket was all that was necessary in cases with no pain. Cough if troublesome often required treatment; dyspnoea was often of evil omen. The President's experience with oxygen inhalation had not been small but was always appointing. An ample supply of fresh air was always desirable. When the heart showed signs of failure digitalis, strophanthus, strychnine, and alcohol were useful remedies. Digitalis and strychnine were the most powerful in his hands and alcohol was inferior to strychnine as a stimulant. For insomnia paraldehyde given by the mouth or rectum was one of the best hypnotics. Opium in any form or dose he shrank from administering in the

Abdominal hysterectomy was performed with some difficulty occasioned by the shortness of the broad ligaments resulting from the previous operation and the presence of enlarged pelvic glands which were only recognised on opening the abdomen. The pelvic glands were removed, those in the obturator canal forming a mass two inches long and half an inch broad. Sections of the cervix showed early adenocarcinoma, some of the acini being free from infiltration. There was definite carcinoma in the obturator and pelvic glands. The uterus contained pus and sections of its wall showed round-celled infiltration with destruction of the endometrium. The patient made a good recovery. The case showed that an extensive infiltration might take place in the pelvic glands with very early disease of the cervix.—Dr. Alexander Stookes (Liverpool) mentioned a case of Single Condyloma of the Cervix in a patient five months pregnant. There was no other evidence of syphilis except pigmentation of the thighs.—Dr. Arthur J. Wallace (Liverpool) made a short communication on a Modification in the Technique of Ventrofixation of the Uterus. The subsequent occurrence of intestinal obstruction in a patient on whom he had performed ventrofixation as well as recorded cases of a similar accident in the practice of some other operators led him to modify his procedure in the technique of the operation. He had noticed that when occasion arose for opening the abdomen of patients who had previously been subjected to this operation a window existed in the utero-vesical pouch below the suspended uterine body. This space would sometimes admit four fingers and through it a loop of bowel could readily pass. To obviate this a complete peritoneal diaphragm was formed from the vesical and utero-vesical peritoneum before suspending the body of the uterus.

HUNTERIAN SOCIETY.—A meeting of this society was held on March 13th, Mr. John Poland, the President, being in the chair.—Dr. George Carpenter read a paper on Nephritis in Infants. According to some American authors albuminuria with passage of casts was common in infants, especially during the course of gastro-intestinal disorders. In Dr. Carpenter's own experience, however, albuminuria in infants was rare; he found it in only two out of 62 cases in the out-patient room. In both these cases there was a marked diminution in the amount of chlorides in the urine. Cases of nephritis undoubtedly occurred in infants, with the usual signs and symptoms. The disease might begin during intra-uterine life. Syphilis played some part in the etiology; there was retarded development of the kidneys in congenital syphilis. Some other toxins might also be a cause of the disease. An important point to remember was that in infantile nephritis, whether of syphilitic origin or not, the kidneys might appear to be normal to the naked eye.—Dr. David B. Lees read a paper on the Administration of Salicylates. He considered that sodium salicylate was as directly antagonistic to acute rheumatism as was mercury to syphilis or quinine to malaria. The drug was often given in doses which were really quite inadequate, because it sometimes caused unpleasant symptoms, and also because there was a prevalent idea that salicylates acted as cardiac depressants. As regards the unpleasant symptoms, the occurrence of which, except vomiting, was rare in children, omission of two or three doses usually lead to their disappearance. Dr. Lees always gave double doses of sodium bicarbonate—e.g., ten grains of bicarbonate of sodium with five grains of salicylate of sodium, which was not a cardiac depressant. The dose should be increased daily or every second day until the maximum was reached. In adults this might be 450 grains in 24 hours. One of Dr. Lees's patients, a boy, aged 15 years, took 600 grains in 24 hours, and then 500 grains six days a week for three weeks. There was no need to discontinue the drug during an attack of pericarditis. If sodium salicylate was given without sodium bicarbonate a condition of acid intoxication very much resembling diabetic coma might be produced. This condition might also be produced by aceto-salicylic acid. In chorea small doses of sodium salicylate were not much good; the dose should be from 200 to 300 grains per diem. Aceto-salicylic acid was especially useful in chronic cases. The objection to this drug was that it could not be given with an alkali.—Mr. Harold L. Barnard read a paper on Intussusception, based on an analysis of 187 cases operated on at the London Hospital. 135 occurred in babies under one year old, 165 under ten years of age. Only four cases occurred in infants under the age of three months. 131 patients were male and 56 were female. He considered that

two factors of great importance in the etiology were lack of nervous control of the ileo-colic sphincter and hypertrophy of the lymphatic nodules of the lower end of the ileum. Prolapse of the mucous membrane of the ileum through the ileo-colic sphincter might occur, like prolapse of the rectal mucous membrane through the anus, and act as the starting-point of the intussusception. The diagnosis was usually easy, but colitis might simulate intussusception and vice versa. The best treatment was immediate operation, though according to Mr. McAdam Eccles's statistics the results of injection were just as good.—Mr. Douglas Drow, Mr. Hugh M. Rigby, Mr. Hugh Lett, and Mr. Hugh Davies discussed the paper. They were none of them willing to accept Mr. Barnard's theory of the causation of intussusception as explaining all cases, as cases in which the caecal coli formed the apex of the intussusception were not uncommon. They were all of opinion that preliminary injection or inflation was useless, as although these methods of treatment often effected partial reduction they did not effect complete reduction.

INCORPORATED SOCIETY OF MEDICAL OFFICERS OF HEALTH.—A meeting of this society was held on March 8th, Dr. D. S. Davies, the President, being in the chair.—Dr. J. E. O'Connor, barrister-at-law, read a paper upon Combined Sanitary Districts. He said that the chaotic and disorganised state of the sanitary medical service had long since become a by-word and that by its improvement the public, and especially the poor, would be greatly benefited. With a view to securing such improvements he recommended the giving of power to the Local Government Board compulsorily to combine sanitary areas for the purpose of appointing a joint medical officer of health; the consolidating of appointments of medical officers of health with supervision of their salaries by the Local Government Board; the payment of official expenses such as the cost of travelling from one part of a district to another; and the provision of clerical assistance. At the present time combined districts appointing whole-time medical officers of health embrace about one-sixth of the area of the country. In Dr. O'Connor's opinion efficiency in rural sanitary administration would be most easily and effectively obtained by combining the remainder of the lesser urban and rural districts. He considered that there was no need for the sweeping alterations in local government recommended in the recent report of the Select Committee on the Housing of the Working Classes—alterations which, apart from the widespread dissatisfaction which they would engender in the precise class that they were intended to benefit, were open to many administrative objections. If the committee had obtained evidence from the members of the Society of Medical Officers of Health who were engaged in the administration of the Public Health Acts in country districts it would have learned that the necessity for administrative improvement was even greater in the small urban districts which it left untouched than in the rural districts which it would extinguish. If it had had before it evidence as to the disabilities under which even the medical officers of combined districts suffered it might have spared its censure on officials who were the victims of inept legislation and might have directed more attention to the indifference of successive Governments to the administrative supervision of the public health. He did not consider that the county was a suitable unit for the apportionment of duties among medical officers of health but advocated the formation of more or less arbitrary combined districts of about 500 square miles in area and with a population of about 100,000. A district of this size he considered could be supervised by one medical officer of health provided he was given suitable clerical assistance.—Mr. Herbert Jones said that the medical inspectors of the Local Government Board, when advising a combination of sanitary districts, were in the habit of stating that the services of a "young and active medical officer of health could be secured at a salary of £500 per annum." This salary would, however, in reality be reduced by official expenses to less than £400.—Mr. W. Gruggen stated that a large district in Hertfordshire had become disintegrated through rural areas becoming urban districts and a local medical officer of health had been appointed.

MANCHESTER MEDICAL SOCIETY.—A meeting of this society was held on March 6th, Dr. S. Moritz, the President, being in the chair.—Dr. Moritz delivered his presidential address on the Diagnosis of Pulmonary Tuberculosis in its Earlier Stages. He pointed out that though

of the brain or cord. On microscopic examination some small vessels of the cortex in the Rolandic area were found to be thrombosed; in others collections of cells with oval nuclei lay heaped up in the perivascular lymphatic spaces. The spinal cord presented nothing abnormal. The cerebro-spinal fluid was examined bacteriologically for Wassermann's cocoon (diplococcus rheumaticus), but with negative results. The cultures remained sterile. No other organ presented any abnormality except the heart, which was small and in an atrophied condition. The mitral and other valves were not inflamed. Dr. Finny called attention to the agreement between the clinical inference that rheumatism and chorea were due to the same poison and the recent bacteriological work of Poynton and Holmes, which demonstrated that the diplococcus of rheumatism was present in the brain and membranes of the cord, as well as in the fringe of vegetation around the mitral orifice and in the mitral valve itself—so commonly found in chorea and in rheumatism. Thus the same micro-organism has been found in various organs—brain, spinal cord, and heart. This organism, termed the diplococcus rheumaticus, has been found in rheumatism and in chorea and according as the toxin produced by it attacked the psychical or the motorial centres of the human subject, so the case would be characterised by great mental disturbance (mania) or by violent choreic muscular movements or both.

Dr. J. CRAIG said that chorea was now described rightly as a specific fever. There was always a certain amount of acute dilatation of the heart in the early stage, with a cardiac murmur that would subsequently disappear. Chorea was merely a complication or manifestation of the rheumatic state. As regards treatment he had modified his belief in the administration of large doses of arsenic.

Dr. THOMAS G. MOORHEAD read an account of a case of Moveable Spleen.

BRITISH GYNÆCOLOGICAL SOCIETY.—A meeting of this society was held on March 14th, Mr. W. D. Spanton, the President, being in the chair. The President showed a specimen of Sarcoma of the Parovarium removed from a patient, aged 42 years, who had been married 16 years, had two children, and one miscarriage 12 years ago. Her health was good until five years ago when she had neuritis of the limbs and head. On opening the abdomen a parovarian cyst was found in the left mesosalpinx. The cyst wall was extensively infiltrated with spindle-celled sarcomatous growth probably of endothelial origin. The growth was removed and the patient made a good recovery. The President also showed a specimen of large Uterine Myoma with Sarcomatous Outgrowth, removed by abdominal hysterectomy from a widow, aged 49 years. Convalescence was satisfactory. Dr. J. A. Mansell Moullin exhibited a Fibroid Uterus containing a foetus of four months removed from a patient, aged 28 years, who was pregnant for the first time and complained of great abdominal pain and tenderness. Examination suggested ectopic gestation. When the abdomen was opened a cervical fibroid was found which would probably have interfered with delivery at term. Dr. H. M. Macnaughton-Jones showed a specimen of carcinoma of the vagina from a patient who afterwards developed carcinoma of the ovary. Mr. F. Bowreman Jessett exhibited a specimen of Carcinoma of the Ovary involving the sigmoid flexure removed from a patient, aged 48 years, who complained of a vaginal discharge which occurred irregularly, being sometimes sanguineous and at other times watery. She was a healthy-looking, well-nourished, active woman. No abnormality was discovered on abdominal examination, but by the vagina the cervix was found to be eroded and thickened, and bimanually a small tumour was found connected with the posterior surface of the uterus which was enlarged but quite mobile. As the discharge seemed to come from the erosion local treatment was recommended with good result. 16 months afterwards an abdominal tumour was discovered extending nearly to the umbilicus and somewhat fixed. This was connected with a tumour in the pouch of Douglas, closely attached to the posterior surface of the uterus. Operation was advised and on opening the abdomen a large tumour presented itself with numerous adhesions to intestines and omentum. After separating these the tumour was found to be so closely adherent to the sigmoid flexura that it was necessary to resect the portion of intestine involved.

Convalescence was complicated by tympanites and constipation which required reopening of the wound. In 14 days the temperature rose and pain became severe. These symptoms were followed in a few days by a fecal fistula at the lower angle of the wound. The fistula closed in a few weeks and the patient progressed satisfactorily. The growth proved to be an alveolar carcinoma. Mr. E. Stanmore Bishop read a paper entitled "Mobile Kidney with a Description of an Operation for Anterior Nephropexy." The only form of importance was the wandering kidney. Two stages existed, the first being one of descent and the second that of loosening of the ureteral attachment to the spine. As the result of the first there was bending of the ureter and subsequently stagnant urine, then kinking of vessels and dragging of the duodenum and biliary ducts. The results of the second stage on the left side were traction on the pericardium through the diaphragm with anginal attacks, constipation and sapremia, followed by hysteria and neurasthenia. The objections to the posterior methods of operating were stated. In any further method the kidney should be supported from below and be placed at a proper height. Through a transverse incision in front the liver was raised and the hepatic flexure was depressed. The kidney was pushed up to its proper level. A transverse incision was made through the peritoneum and the capsule was cut through in a curved line which was then turned down and the edge fixed. The peritoneum was then replaced and sewn up. An incision was made through the skin and tissues posteriorly over the lumbar muscles. Fixation sutures of chromic or iodised gut were passed through the kidney from the front, with due regard to vessels and nerves, to the posterior incision, and were there tied, after which both wounds were closed. This operation had been performed ten times with satisfactory results in all but the first case, where the capsule was not utilised.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.—A meeting of this society was held at Sheffield on March 15th, Dr. Edward O. Croft, the President, being in the chair. Dr. Archibald W. Cuff (Sheffield) described a case of Ruptured Isthmic Ectopic Gestation. The patient, who was 34 years of age and had been four times pregnant, had two miscarriages each at about the fifth month. Menstruation was regular up to the last period which was a week late. After an interval of 30 days she was suddenly seized with intense pain in the lower abdomen which rapidly became worse. There was considerable collapse, the pulse-rate was 120, the temperature was sub-normal, and respiration was sighing. Abdominal section was performed within six hours of the onset of the first symptom. The abdomen contained free blood and the isthmus of the right Fallopian tube was found to be the seat of an early gestation which had ruptured. Dr. Cuff also related a case of Uterine Fibroid in a woman, 35 years of age, and four months pregnant, who suffered from abdominal pain and constant vomiting. Her temperature was 101° F., her pulse-rate was 120, and she looked very ill. The size of the abdominal swelling exceeded that of a four months pregnancy and on the left side a hard, excessively tender swelling could be felt. It could be moved independently of the uterus and this together with the fact that it had rapidly increased in size pointed to its being a solid ovarian tumour with a twisted pedicle. Abdominal section revealed a uterine fibroid of the size of a fetal head springing posteriorly from the left cornu of the uterus. Enucleation was performed and a second and smaller fibroid was removed. Superficial and deep sutures were used to close the uterine incision and the abdominal wall was sutured in three layers. There was no interference with the progress of the pregnancy. Dr. John E. Gemmell (Liverpool) read notes of a case of Early Carcinoma of the Cervix Uteri treated by Abdominal Hysterectomy and Pelvic Dissection. Five years previously he had operated on the patient for an adenomatous ovarian cyst on the left side and hydrosalpinx on the right side. She remained in good health until the summer of 1906, when she began to have pain in the left leg and thigh. On admission to a hospital in January, 1907, there was marked cedema of the left leg. Per vaginam the uterus was found to be as large as in the third month of pregnancy, of soft solid consistence and fixed; the cervix was hard and irregular and bled easily. Early epithelioma of the cervix was diagnosed with fibroid of the uterus.

the disease was far advanced and the patient exhausted. Judging from the very conflicting literature on the subject and from his own observations, he was of opinion that pregnancy had a very uncertain effect upon the course of Graves's disease, sometimes ameliorating but more often aggravating it. There was, therefore, no reason to preclude girls with exophthalmic goitre from marriage.—The paper was discussed by the President, Dr. A. H. K. Barbour, Dr. N. T. Brewis, Dr. James Ritchie, and others.—Dr. David Newman described several cases of Lesion of the Bladder, illustrating the cystoscopic appearances by the opaque projector. The first three cases were examples of sacculated bladder, in two of which the diverticulum contained a calculus. In one of them the calculus would probably have escaped observation without the assistance of the cystoscope. The mucous membrane of the bladder was practically normal. The colour, except immediately around the opening of the sacculi, was pale, but the lips of the opening were deeply congested, rounded, and thickened, and in contrast to the bright red lips of the opening the calculus was seen as a pale white object. Dr. Newman also described three cases illustrating certain causes of painful micturition in women, not usually recognised. In the first case there was at the margin of the neck of the bladder a crowd of very delicate filar processes with bulbous ends extending from the margin inwards for a distance of about a third of an inch; the papillae were pale in colour, except at the tips, where they were bright red and almost of the colour of blood. They were quite translucent and presented an edematous appearance. The symptoms were practically those of a vesical calculus; removal of the outgrowth, which was of inflammatory origin, gave complete relief. In another case the lesions were little nodular growths not larger than a barley-corn, oval in shape, of a bright red colour, and protruding from the mucous membrane very much like the granulations in chronic pharyngitis. This lesion was frequently seen in rheumatic subjects and unless a cystoscopic examination was made the symptoms might be assigned to other causes.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society was held on March 7th. Dr. W. C. Chaffey, the President, being in the chair.—The President showed a child, aged seven years, with a Constant Slow Pulse, 40 to 50 beats in the minute, also an apical systolic murmur, but no dilatation of the heart. He also showed a child with Spastic Paraplegia which he considered to be due to congenital abnormality in the pyramidal tracts and not to injury at birth.—Dr. E. Hobhouse showed a case of Spastic Paraplegia (Diplegia) in a child.—Dr. Walter Broadbent showed a man with Charcot's Disease of the Left Knee-joint, there being painless effusion, grating of the bones, and looseness of the ligaments. The patient had Argyll-Robertson pupils and no knee-jerks, but there was no ataxia.—Dr. D. G. Hall showed a similar case of Charcot's Disease of the Knee and a remarkable case of Charcot's Disease of the Right Shoulder which had come on painlessly and very rapidly in which an x-ray photograph showed considerable loss of the head of the humerus; the arm could be moved into almost any position, natural or unnatural. He also showed a woman with Leontiasis Ossea of the Face and Tertiary Nodes of the Tibia and Right Femur.—Dr. A. J. Hutchison showed photographs and microscopic specimens from a case of Osteosarcoma of both Superior Maxilla which at first simulated double antral suppuration.—Dr. Broadbent read a paper on Some Myocardial Diseases, pointing out that myocarditis was often neglected because there was no cardiac murmur. He also dealt with the physical signs of cloudy swelling, the shortening and weakening of the first sound, and the variations in different acute diseases, and laid stress on the dangers of dilatation of the stomach in these diseases.—The paper was discussed by the President, Dr. C. H. Benham, Dr. Hutchison, Dr. A. M. Dalry, Dr. H. C. Lecky, and Mr. W. D. Calvert.—Dr. Broadbent replied.

GLASGOW MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society was held on March 1st. Dr. J. Lindsay Steven, the President, being in the chair.—Dr. J. Walker Downie read notes on Six Cases of Sarcoma of the Nose. The masses of the ethmoid, including the middle turbinal, or in some the septum involved. The growths resembled simple mucous polypi. Epistaxis, pain during any manipulation with

the tumour, and any distension and hypertrophy of the nasal bones were suspicious symptoms and called for careful microscopic examination of the tumour. Early diagnosis and thorough removal were very important. Where the tumour was entirely intranasal it should be removed by punch forceps, cauteries, and the electric cautery. Where the septum was involved and the area widespread Roux's operation should be performed.

ÆSCULAPIAN SOCIETY.—A meeting of this society was held on March 15th. Dr. J. R. T. Conner, the President, being in the chair.—Mr. C. Gordon Watson read a paper on the Treatment of Tuberculous Disease of the Knee. He said that in early cases rest should be enforced, as this checked inflammation and so prevented deformity. A moulded undressed leather splint should be worn for six months after all active symptoms had subsided. Tuberculin injections and passive congestion might be used in future in the treatment of tuberculous arthritis. Suitable hygienic conditions were most important. The following generalisations briefly expressed Mr. Watson's conclusions on the operative treatment. Mixed infection spelt doom to the joint. There were two knees worth having: the moveable, when it was stable; and the fixed, when it was straight. Crasions seldom produced either. Fibrous ankylosis spelt fixation and failure. The tubercle bacillus sometimes wrecked a child's joint; but erosion and excision were the worst offenders. In the young adult excision was very good; in the old amputation made the best of a bad job.—Dr. W. Langdon Brown read notes of a case of Frontal Cerebral Abscess and showed the specimen. He also showed a microscopic specimen of an Anglo-mammoma.—Mr. W. Campbell McDonnell read notes of a case for diagnosis.

Reviews and Notices of Books.

Judicial Statistics, England and Wales, 1905. Part I., Criminal Statistics. London: Wyman and Sons, 1907. Pp. 211. Price 2s.

THIS volume of criminal statistics for 1905 contains the usual information relating to the movement of crime and to the judicial proceedings in criminal cases during the year in question, together with the customary returns as to coroners' inquests, reformatory and industrial schools, criminal lunatics, and habitual drunkards. The figures are arranged in the tabular form adopted on the revision of the criminal statistics in 1892. The tables are preceded by a lengthy and interesting introduction written by Sir John Macdonell, C.B., Master of the Supreme Court, who, it will be recollected, contributed a valuable introduction to the statistics for 1893. On the present occasion he has dealt exhaustively with the figures for the year under review and has also devoted special consideration to certain points of general sociological interest as to which he has been at pains to obtain supplementary information. As a result, his introduction forms one of the most remarkable studies of crime that have appeared in this country for some years.

The first question usually asked with reference to these statistics is, What do they tell us of the tendency of crime? The answer suggested by the official figures is that during the last few years crime, at least in its more serious forms, has increased absolutely and relatively to population. In 1905 the number of indictable offences reported to the police and the number of persons tried for such offences were larger than in the preceding year and considerably in excess of the average figures for the period 1901-05, and the frequency of serious crime during that quinquennial period was again considerably greater than in the five years 1896-1900. If, however, we carry the comparison back over a longer term of years we find that the general trend of movement has been decidedly downwards. Thus, while the average number of persons per 100,000 of the population tried for indictable offences in 1901-05 was 175, in 1857-60 it was 263. In this more extended survey the year 1899 is seen to

the finding of tubercle bacilli in the sputum made the diagnosis of pulmonary tuberculosis absolutely certain, the diagnosis often had to be made when tubercle bacilli were not found, for there might be no sputum, or it might contain no bacilli or show them only at intervals, this latter condition being of frequent occurrence. Iodide of potassium and a wet pack sometimes promoted the expectoration of characteristic sputa. The serum diagnosis of Arloing and Courmont gave in 12 per cent. of tuberculous cases a negative, and in 33 per cent. of clinically non-tuberculous cases a positive, reaction. Injections of tuberculin were not always free from danger and a positive reaction only proved the presence of a tuberculous focus somewhere, which focus might moreover be active or latent. The President then gave the particulars and the results so far obtained by opsonin testing at the Delamere Sanatorium. These led him to the conclusion that the opsonic index formed no trustworthy diagnostic sign for pulmonary tuberculosis as it might be normal, high, or low. French's sign also was of no help; after small injections of tuberculin, namely, there need not be a long-lasting negative phase in the phthisical, as this negative phase was occasionally absent and frequently found of short duration. The President concluded that the diagnosis of early pulmonary tuberculosis must still be made not by bacteriological methods but by the consideration of the symptoms and physical signs. He reviewed the former, laying special emphasis on the significance of persistent rises of temperature, hæmoptysis, digestive troubles, &c. In regard to the last he recommended careful percussion and auscultation over the posterior apices of the lung after the patient had been at rest and before he had been made to breathe deeply, as only in this way some abnormalities in the sounds due to temporary obstruction of a bronchus could be heard, which sounds disappeared after several deep inspirations. He further reviewed the significance of other physical signs, as well as the results of Roentgen ray examination.—Mr. J. E. Platt related the case of a man, aged 60 years, in whom he had performed the operation of gastro-jejunostomy for a carcinoma of the pylorus causing marked obstruction. On the fourth day after operation the left submaxillary gland had become swollen and painful and on the sixth day the left parotid gland also. A few days later the glands were incised and considerable quantities of pus were evacuated. After the operation the patient had been greatly distressed by an extremely dry condition of the mouth. The abdominal wound had healed by primary union, and with the exception of the suppuration in the salivary glands the patient had made a good recovery and had had relief from his symptoms for many months after the operation. The pathology of the condition was discussed, and it was pointed out that the suppuration was the result of a septic condition of the mouth and deficient secretion of saliva allowing organisms to travel upwards along the ducts of the salivary glands. In the majority of cases the suppuration had been preceded by a very dry condition of the mouth, and in many cases the patient had been fed for some time by nutrient enemata. The comparative rarity of this affection in the submaxillary gland was referred to.

BRITISH LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL ASSOCIATION.—A meeting of this society was held on March 8th, Mr. Mayo Collier, Vice-President, being in the chair.—Dr. P. H. Abercrombie showed a case of a male, aged 62 years, in whom he had performed Thyrotomy for the removal of Epithelioma of the Right Vocal Cord. The suspicions aroused by the clinical appearances had been made certain on examination by Dr. V. H. Wyatt Wingrave of a piece of the growth removed by Dundas Grant's laryngeal forceps. Operating at an early stage the exhibitor had been able to excise the growth thoroughly.—Dr. Abercrombie also showed another case in which he had performed Thyrotomy two years ago for Epithelioma of the Left Vocal Cord and in which no recurrence had taken place. In both operations he had performed a preliminary tracheotomy and had inserted into the trachea a Hahn's cannula.—Dr. Abercrombie likewise showed a case of "Tuberculoid" Disease of the Left Tonsil in a woman, aged 67 years. The patient went to hospital complaining of sore-throat confined to the left side, of about two months' duration. On inspection the left tonsil was seen to be enlarged and covered with a whitish exudation and at its upper border extending on to the palate was a nodular, ulcerated area. The left side of the palate, the epiglottis, the left arytenoid, and the left ventricular band were

congested and oedematous. The glands at the left angle of the jaw were enlarged and tender. The first explanation of these appearances was that the disease was either tertiary syphilis or malignant disease. The microscopic findings, however, showed, in the opinion of Dr. Wyatt Wingrave, that the tonsil was the seat of granular deposit of the tuberculous type. No tubercle bacilli were found in the tissue.—Mr. Mayo Collier showed a case of Laryngeal Tuberculosis in a male the subject of long-standing tuberculous disease in the lungs and ribs.—Mr. W. J. Chichele Nourse showed a case of Tuberculous Disease of the Larynx in which enormous swelling of the left arytenoid region existed.—Mr. Mayo Collier thought that these cases should be treated by tracheotomy in order to give the larynx rest and time to recover from the severe inflammatory reaction, otherwise the condition would go on from bad to worse until the tumefaction and pain would effectually prevent swallowing, when the patient would rapidly sink from inanition.—Mr. H. S. Barwell and Mr. J. Bark could not agree with Mr. Mayo Collier in his advice. Their experience of tracheotomy had been very discouraging. They preferred to remove the tuberculous masses with punch forceps if the necessity for interference arose.—Dr. Andrew Wylie showed a case of Paralysis of the Left Vocal Cord of Four Years' Duration in a young man due to pressure on the left recurrent laryngeal nerve by large masses of enlarged lymphatic glands in the root of the neck.—Dr. Patrick Dempsey and Dr. S. Horace Law considered the glands in Dr. Wylie's case to be the seat of tuberculous disease.—Dr. D. McKenzie was of opinion from the long persistence, the size, the extreme hardness, and the discrete character of the glandular masses that they were of the nature of lymphadenoma.

SOUTH-WEST LONDON MEDICAL SOCIETY.—A meeting of this society was held on March 13th, Dr. M. Mackintosh, the President, being in the chair. Dr. Herbert P. Hawkins gave an address on Constipation and Dilatation of the Colon with some results of treatment. After briefly detailing the salient features of the condition formerly known as idiopathic dilatation of the colon, Dr. Hawkins showed a typical example and demonstrated the presence of the chief signs. In this case, an infant, aged six months, whose grandfather had been under Dr. Hawkins's care for the same condition and who died from it at the age of 40 years, there was a history of constipation from birth, requiring active interference at the eighth day, alternating with diarrhoea. There had been no vomiting and there seemed to be no pain. The abdomen was distended and a large loop of distended colon ending in the left iliac fossa was well marked and showed peristaltic movements. On examination per rectum the bowel fitted on the finger like a glove and no superior opening could be felt, but a stiff tube could be passed upwards through which small quantities of liquid fecal matter had been drained away. Dr. Hawkins then showed lantern slides illustrating other cases and the anatomical and pathological features of the condition. He maintained that the adult form was of the same nature and origin as that of the child and was to be regarded as a rare and exceptionally long-lived instance of the congenital form. In no case was there an organic obstruction to be found; the dilatation and hypertrophy producing a funnel-shaped portion of colon, of which the lower end was usually in the pelvic colon, led to the supposition that the condition was due to a tight muscular contraction of the bowel in this position, or, what was an equally effective obstruction, paralysis of a segment of the bowel. Patients were, as a rule, in good health until the onset of a fatal toxæmia; it was essential that such cases should be recognised in an early stage, as operative interference might be, and had been, successful. The operation advised was short circumferential bowel to a point below the supposed obstruction; colotomy was not a desirable measure, and the removal of the dilated colon had on some occasions been followed by a fresh dilatation.

EDINBURGH OBSTETRICAL SOCIETY.—A meeting of this society was held on March 13th, Dr. J. W. Ballantyne, the President, being in the chair.—Sir J. Halliday Croome read a paper on Exophthalmic Goitre in its Relation to Gynecology and Obstetrics. He said that his personal experience led him to believe that there was no interdependence between Graves's disease and gross pelvic lesions. Disorders of menstruation were frequently associated with exophthalmic goitre, menorrhagia being the symptom when the disease was early and progressive, and amenorrhœa only when

from an anatomical and a surgical standpoint. Lecture I. is divided into two parts, (1) The Temporal Bone at Birth; and (2) The Surgical Anatomy of the Labyrinth. Under the first heading the bone as a whole, as it appears at birth, is minutely described and subsequently the middle-ear tract and the consistence of the outer antral wall are dealt with. The author points out the paths by which infection may pass from the middle ear to the meninges and also explains why sinus thrombosis is so rare at this time of life. In discussing the surgical anatomy of the labyrinth the operative treatment of Ménière's disease is referred to and the writer takes the hopeful view that in the future sufferers from this disease will receive relief at the hands of the surgeon. In Lecture II. the changes that occur in the bone during growth are set forth at length and amongst other things the reason of the comparatively late development of the mastoid process is explained. Then follow three most instructive chapters on the relation of the lateral sinus to the surface, the consistence of the outer antral wall and mastoid process, and the variations in the middle ear and antrum. From the surgeon's point of view these chapters are quite the best in the book and the illustrations, reproduced from photographs, are beyond criticism. The third lecture is devoted to the surgical anatomy of the structures met with in the performance of the radical mastoid operation. It contains much useful and valuable information relating to guides to the antrum, precautions in opening the antrum, and the relations of the facial nerve in the adult. A brief but concise account of Wallace's and Parry's operations for division of the auditory nerve brings the chapter to a successful termination. The book is profusely illustrated by photographs of the specimens shown at the Hunterian lectures and should prove of great value to the anatomist and to the surgeon.

LIBRARY TABLE.

War with Disease. By FREDERICK F. MACCABE, M.B.Dub., Medical Officer, South of Ireland Imperial Yeomanry. Second edition. London: Baillière, Tindall, and Cox. 1907. Pp. 125. Price 1s. net.—The second edition of this book, which is dedicated, by permission, to Field-Marshal H.R.H. the Duke of Connaught, has, the author says, been demanded much sooner than he had dared to anticipate and he adds that he is indebted for the demand to two factors: first, that a few regiments have ordered a large number of copies for distribution amongst the men of the regiment; and secondly, to favourable notices in the press. He has included in this edition a special lecture on "Health and Fitness," which he delivered to the recruits of the cavalry regiments stationed in Ireland during the year. Since Dr. Maccabe first delivered the lectures contained in this little book he has repeated them to the officers of the Staff College in Camberley. For this audience he went a little more deeply into the scientific reasons for the suggestions made. He has now amplified these parts and has reproduced the lectures as he delivered them at the Staff College. He has added as a second part of this book the introductory lectures which he gave to his ambulance section, in the hope that medical officers of both Yeomanry and Volunteer regiments may adopt the idea of making their ambulance classes of greater use to the regiment and to the public generally than mere renderers of first aid can ever hope to be. Dr. Maccabe has certainly made his chapter on anatomy most interesting and as he says "alive," but we venture to think that he must be joking when he writes that "my South of Ireland Yeomanry class knew their anatomy at the close of the course as well as the average medical student." In commenting on the extracts from Surgeon-General Havard's Report on the Russian Camps in

Manchuria, the author selects three special points: First, the use of soup in camp and on the march, for, as he says, "Hard-working men must have liquid in some form or other. It is to be hoped that in all manœuvres in future the rash will be for the soup-cart and not for the too-often poisoned water-cart." The second point he dwells on is the use of hot, to say nothing of vapour, baths at the front. As his third point he asks medical officers to use their influence to get the hard, indigestible, and very constipating ration biscuit abolished in favour of brown bread, as the Russians have done with such good results. We consider the book to be a valuable one. Each page is well written and the different subjects are presented with a pleasing freshness.

Dissections Illustrated. By C. GORDON BRODIE, F.R.O.S. Eng. With plates drawn and lithographed by PERCY HIGLEY. In 73 coloured plates and 37 diagrams. Second edition, revised. London: Whittaker and Co. Price 25s. net.—Gordon Brodie's "Dissections Illustrated" is an atlas already familiar to many medical men; to those not acquainted with it its nature may best be indicated by saying that the lithographic plates of which it consists closely follow in appearance, colouring, and range the well-known plates of Professor G. V. Ellis but are on a reduced scale. Most of the drawings are from original dissections by the author. In form the atlas is handy and portable and the illustrations convey a very good idea of the head, the neck, and the limbs as seen in ordinary dissections. In comparison with certain atlases of more recent date the illustrations of the thorax and abdomen leave very much to be desired. The central nervous system and the joints and bones are not illustrated at all.

Traité des Variations des Os de la Face de l'Homme et de leur Signification au Point de Vue de l'Anthropologie Zoologique. (Treatise on the Variations of the Bones of the Face in Man and their Signification from the Point of View of Comparative Anthropology.) By Dr. A. F. LE DOUBLE, Professor of Anatomy at the School of Medicine of Tours. Paris: Vigot Frères. 1906. Pp. xx. + 471. Price 25 francs.—The results of an immense amount of painstaking investigation and of wide reading are embodied by Professor le Double in this monograph. The exhaustive way in which the subject is treated will be appreciated when it is realised that a bulky volume of over 450 pages is devoted to the variations and abnormalities of the bones of the face alone. The descriptions are minute and exhaustive; many tables of measurements are given, collected from various sources, and numerous illustrations in the text add to the value of the work. The bearing of the facts of comparative anatomy on the variations met with is discussed at length in every case. There is included a short appendix to a former treatise by the same author on the variations of the bones of the cranium in man. The book is provided with full indices, and to those interested in the subject will prove a veritable mine of information. The author claims, and we believe correctly, that it is the only work of the kind which at present exists.

Hygromedry. By HENRY EMERSON WETHERILL, M.D. Philadelphia: Published by the Author (Press of W. Ellis Johnson and Co.). Fourth edition. 1906. Pp. 82. Price \$2.50.—The new word in the title of Dr. Wetherill's book denotes what he elsewhere calls medical hygrometry, or the quantitative estimation of the water vapour given off from limited areas of the skin. He uses two instruments for this purpose. One of them, called the hygromed or medical hygroscope, is a small shallow circular box of aluminium, with eight holes in the bottom. It has a transparent celluloid top and contains a graduated scale over which a pointer is moved by the contraction and elongation of a hygrosopic membrane. The perforated portion of the instrument is placed over the area of skin to be tested and the water vapour entering the box moves the pointer

mark the extreme limit of the receding movement which was observable in serious crime during the last quarter of the nineteenth century; the first years of the present century have shown an opposite tendency, though the increase in crime is so far relatively slight. The movement of crime taken as a whole is, however, of very little real significance to the social observer; to judge of its meaning it is necessary to discriminate between the various forms of delinquency, as we can in some measure do by means of the legal classification of offences, though of course their correspondence with psychological and ethical divisions is very imperfect. When we look at the matter from this point of view we find that the increase in serious crime is confined to offences of acquisitiveness, while crimes of violence and of lust have, on the contrary, diminished in frequency. The enormous numerical preponderance of crimes of acquisitiveness—they constitute nearly nine-tenths of the total amount of indictable crime—makes their oscillation decisive of the general movement. For the most part offences of this class are dependent on economic conditions and vary inversely with the prosperity of the country. The editor has brought out this relationship very strikingly in a diagram showing the number of receiving orders in bankruptcy and the number of persons tried for larcenies per 100,000 of the population in each year from 1885 to 1905; the remarkable likeness between the two curves is strongly suggestive of a connexion between this mode of delinquency and the prevalent state of trade. The other varieties of crime are, of course, much less immediately related to economic conditions and are, moreover, very often influenced by such conditions in a quite different way, so that it is nowise surprising to find that very frequently, as was the case in 1905, their movement does not coincide with that of crimes of acquisitiveness. Of the more purely impulsive disorders of conduct attempts to commit suicide also showed an increase in frequency, the number of such attempts in 1905 being 2342, the highest figure yet recorded. In this connexion it may be remarked that actual suicide also increased, the number of deaths under that head being 3515, as against 3327 in 1904. The slight check to the upward movement in these two manifestations of suicidal impulse, which was apparent in 1904, has not, therefore, been maintained.

Non-indictable offences, which include a large number of acts and omissions that are only criminal in a technical sense, are of relatively small value as indications of the moral health of the community. It is worth noting, however, as a confirmation of the inferences drawn from the statistics of indictable crimes, that assaults, wilful damage to property, and cruelty to children, which are probably allied to the more serious crimes of violence, have, like these latter, decreased in frequency; the number of prosecutions for assault in 1905 (52,811) is, indeed, the smallest on record. There has also been a considerable fall in the prosecutions for drunkenness, which numbered 219,276, as against 227,403 in 1904. Whether owing to a real growth in vagrancy, or as a result merely of increased activity on the part of the police, stimulated by the greater interest which has been taken in the question recently, there has been a decided rise in the number of convictions for begging and sleeping out, the total for the year (27,496) being the largest yet recorded. From an analysis of the figures it appears that the large majority (over 90 per cent.) of offenders of this class are men, and that nearly half of them are between 21 and 40 years of age. The editor suggests that the striking predominance of males in the tramp class would go to prove that scarcity of employment cannot be a very important factor in causing vagrancy; but against this we have to remember that prostitution is available as an alternative for women. The growing complexity of social life leads, of course, to the creation of many new crimes, so that in certain classes of

non-indictable offences the figures show an increase. An interesting illustration of this point is to be seen in the prosecutions in relation to motor-cars which, in 1905, were nearly twice as numerous as in the preceding year.

The number of criminal lunatics received during the year was 196, which is considerably below the average. Of this number 114 were certified after conviction, while 15 were certified before trial, 28 were found insane on arraignment, and 39 were found "guilty but insane." As in previous years, there is a striking difference between the more serious crimes of violence and the other classes of delinquency, with respect to the time when the existence of insanity is ascertained, over 98 per cent. of insane homicidal offenders being certified at or before trial, while the corresponding proportion in non-homicidal crime is less than 25 per cent. This difference may be in part explained by the course which is sometimes taken of dismissing the criminal charge in minor offences by insane persons and certifying the culprit as a pauper lunatic; it is to be regretted that no statistical information is given as to the number of cases so dealt with and the character of the offences.

Of the matters discussed in detail by Sir J. Macdonell the statistics of homicide are specially interesting. Including under that term cases of murder and of manslaughter, he shows that these offences have decreased considerably within the last 20 years, the number per 100,000 of the population having fallen from 1.32 in 1886-90 to 0.84 in 1905. Homicide is, as a rule, a crime of men, the proportion of women amongst convicted murderers not being more than about 1 in 7. In Scotland and Ireland there is a similar predominance of males. Amongst the victims, on the other hand, women are in a majority of 3 to 2. With regard to age incidence, it is found that about 59 per cent. of the persons convicted are from 21 to 40 years old. A remarkable point is the frequency of a sexual tie between the murderer and his victim; thus, of 487 men sentenced to death since 1886, 124 had killed their wives and 115 their sweethearts or mistresses. Homicidal crime is met with chiefly in the lower order of the labouring population of seaports and manufacturing towns; it is rarely committed by habitual criminals. The generally impulsive character of the crime is shown in the frequent choice of such domestic weapons as chairs, choppers, pokers, and the like; poison is rarely used—in only about 6 per cent. of cases. More murders are committed on Saturday than on any other day of the week, while the lowest figure is found on Sunday. In about one-fifth of the cases the crime is committed between 10 P.M. and midnight, and in nearly half between 8 P.M. and 2 A.M.

On the questions of juvenile and female offenders, on recidivism, and on the characters of the criminality in certain large cities, Sir J. Macdonell also gives much interesting information which, however, hardly admits of summarising. The absence of data relative to the criminal individuality and the insufficiency of details on several points, such as the different varieties of recidivism, the sexual incidence in attempts to commit suicide, and so on, to which attention was drawn last year, must still qualify our praise of a volume which, even with these slight defects, can compare favourably with the criminal statistics of any European State.

The Surgical Anatomy of the Temporal Bone from Birth to Adult Life. By ARTHUR H. CHEATLE, F.R.C.S. Eng., Aural Surgeon to King's College Hospital and to King Edward VII.'s Hospital for Officers. London: J. & A. Churchill. 1907. Pp. 131. Price 5s. net.

This book is the outcome of the Hunterian lectures delivered by Mr. Cheatle at the Royal College of Surgeons of England in 1906 and, as might be expected, contains a very thorough and accurate description of the temporal bone both

from an anatomical and a surgical standpoint. Lecture I. is divided into two parts, (1) The Temporal Bone at Birth; and (2) The Surgical Anatomy of the Labyrinth. Under the first heading the bone as a whole, as it appears at birth, is minutely described and subsequently the middle-ear tract and the consistence of the outer antral wall are dealt with. The author points out the paths by which infection may pass from the middle ear to the meninges and also explains why sinus thrombosis is so rare at this time of life. In discussing the surgical anatomy of the labyrinth the operative treatment of Ménière's disease is referred to and the writer takes the hopeful view that in the future sufferers from this disease will receive relief at the hands of the surgeon. In Lecture II. the changes that occur in the bone during growth are set forth at length and amongst other things the reason of the comparatively late development of the mastoid process is explained. Then follow three most instructive chapters on the relation of the lateral sinus to the surface, the consistence of the outer antral wall and mastoid process, and the variations in the middle ear and antrum. From the surgeon's point of view these chapters are quite the best in the book and the illustrations, reproduced from photographs, are beyond criticism. The third lecture is devoted to the surgical anatomy of the structures met with in the performance of the radical mastoid operation. It contains much useful and valuable information relating to guides to the antrum, precautions in opening the antrum, and the relations of the facial nerve in the adult. A brief but concise account of Wallace's and Parry's operations for division of the auditory nerve brings the chapter to a successful termination. The book is profusely illustrated by photographs of the specimens shown at the Hunterian lectures and should prove of great value to the anatomist and to the surgeon.

LIBRARY TABLE.

War with Disease. By FREDERICK F. MACCABE, M.B.Dub., Medical Officer, South of Ireland Imperial Yeomanry. Second edition. London: Baillière, Tindall, and Cox. 1907. Pp. 125. Price 1s. net.—The second edition of this book, which is dedicated, by permission, to Field-Marshal H.R.H. the Duke of Connaught, has, the author says, been demanded much sooner than he had dared to anticipate and he adds that he is indebted for the demand to two factors: first, that a few regiments have ordered a large number of copies for distribution amongst the men of the regiment; and secondly, to favourable notices in the press. He has included in this edition a special lecture on "Health and Fitness," which he delivered to the recruits of the cavalry regiments stationed in Ireland during the year. Since Dr. Maccabe first delivered the lectures contained in this little book he has repeated them to the officers of the Staff College in Camberley. For this audience he went a little more deeply into the scientific reasons for the suggestions made. He has now amplified these parts and has reproduced the lectures as he delivered them at the Staff College. He has added as a second part of this book the introductory lectures which he gave to his ambulance section, in the hope that medical officers of both Yeomanry and Volunteer regiments may adopt the idea of making their ambulance classes of greater use to the regiment and to the public generally than mere renderers of first aid can ever hope to be. Dr. Maccabe has certainly made his chapter on anatomy most interesting and as he says "alive," but we venture to think that he must be joking when he writes that "my South of Ireland Yeomanry class knew their anatomy at the close of the course as well as the average medical student." In commenting on the extracts from Surgeon-General Hayward's Report on the Russian Camps in

Manchuria, the author selects three special points: First, the use of soup in camp and on the march, for, as he says, "Hard-working men must have liquid in some form or other. It is to be hoped that in all manoeuvres in future the rush will be for the soup-cart and not for the too-often poisoned water-cart." The second point he dwells on is the use of hot, to say nothing of vapour, baths at the front. As his third point he asks medical officers to use their influence to get the hard, indigestible, and very constipating ration biscuit abolished in favour of brown bread, as the Russians have done with such good results. We consider the book to be a valuable one. Each page is well written and the different subjects are presented with a pleasing freshness.

Dissections Illustrated. By O. GORDON BRODIE, F.R.C.S. Eng. With plates drawn and lithographed by PERCY HIGLEY. In 73 coloured plates and 37 diagrams. Second edition, revised. London: Whittaker and Co. Price 25s. net.—Gordon Brodie's "Dissections Illustrated" is an atlas already familiar to many medical men; to those not acquainted with it its nature may best be indicated by saying that the lithographic plates of which it consists closely follow in appearance, colouring, and range the well-known plates of Professor G. V. Ellis but are on a reduced scale. Most of the drawings are from original dissections by the author. In form the atlas is handy and portable and the illustrations convey a very good idea of the head, the neck, and the limbs as seen in ordinary dissections. In comparison with certain atlases of more recent date the illustrations of the thorax and abdomen leave very much to be desired. The central nervous system and the joints and bones are not illustrated at all.

Traité des Variations des Os de la Face de l'Homme et de leur Signification au Point de Vue de l'Anthropologie Zoologique. (Treatise on the Variations of the Bones of the Face in Man and their Signification from the Point of View of Comparative Anthropology.) By Dr. A. F. LE DOUBLE, Professor of Anatomy at the School of Medicine of Tours. Paris: Vigot Frères, 1906. Pp. xx.—471. Price 25 francs.—The results of an immense amount of painstaking investigation and of wide reading are embodied by Professor le Double in this monograph. The exhaustive way in which the subject is treated will be appreciated when it is realised that a bulky volume of over 450 pages is devoted to the variations and abnormalities of the bones of the face alone. The descriptions are minute and exhaustive; many tables of measurements are given, collected from various sources, and numerous illustrations in the text add to the value of the work. The bearing of the facts of comparative anatomy on the variations met with is discussed at length in every case. There is included a short appendix to a former treatise by the same author on the variations of the bones of the cranium in man. The book is provided with full indices, and to those interested in the subject will prove a veritable mine of information. The author claims, and we believe correctly, that it is the only work of the kind which at present exists.

Hygromedry. By HENRY EMERSON WETHERILL, M.D. Philadelphia: Published by the Author (Press of W. Ellis Johnson and Co.). Fourth edition. 1908. Pp. 82. Price \$2.50.—The new word in the title of Dr. Wetherill's book denotes what he elsewhere calls medical hygroscoy, or the quantitative estimation of the water vapour given off from limited areas of the skin. He uses two instruments for this purpose. One of them, called the hygromed or medical hygroscope, is a small shallow circular box of aluminium, with eight holes in the bottom. It has a transparent celluloid top and contains a graduated scale over which a pointer is moved by the contraction and elongation of a hygroscopic membrane. The perforated portion of the instrument is placed over the area of skin to be tested and the water vapour entering the box moves the pointer

to a position on the scale which is taken as marking the relative humidity. The other method consists in the use of filter paper which has been treated with cobalt chloride, a salt progressively varying in colour from pale pink when moist to blue when well dried. A piece of this prepared paper is placed on the skin under glass, and after ten minutes its hygrometric condition is estimated by comparison with a standard graduated scale of tints. Dr. Wetherill gives a variety of details with respect to the clinical use of these contrivances. He has found, for instance, that the moisture of the skin gradually decreases with the oncoming of uræmia and sufficient notice is thereby given for commencing treatment. He says that there seems to be a normal diurnal change in the moisture of the skin not entirely accounted for by the daily change of temperature. In one case mental (not muscular) fatigue was accompanied by an increase of moisture in the palms of the hands. Short descriptions of hygrometric apparatus suggested by other investigators, as well as an account of a simple form of centrifuge, will be found in Dr. Wetherill's pages.

A Second German Course for Science Students. By H. G. FIEDLER, Professor of German at the University of Birmingham, and F. E. SANDBACH, Lecturer in German at the University of Birmingham. London: Alexander Moring, Limited. 1906. Pp. 76. Price 2s. 6d.—This is a companion volume or supplement to a similar work by the same authors which was reviewed in THE LANCET of June 23rd, 1906, p. 1764. It is a collection of 24 typical extracts from articles published in recent numbers of well known German scientific periodicals; almost all of them deal with questions of chemistry and physics, but there is one on the technology of iron and steel and one on the analysis of graphic curves by the planimeter. The notes at the end of the book explain various German grammatical peculiarities and give some translations of unusual words. It is generally found that much practice is required before a foreigner can read a German author easily and still more practice before he can produce a readable and idiomatic translation in his own language. The present volume is an excellent introduction both to reading and translation. Roman characters are used throughout; in the reference to the combination ss (a single letter in German character) on p. 67 we should have liked to see some mention of the practice (happily rather uncommon) of transliterating it as sz, so that "dass" becomes "dasz" and "gross" becomes "grosz."

JOURNALS AND MAGAZINES.

The Biochemical Journal.—The February number of this journal contains, in addition to two papers of purely botanical interest, the following papers of physiological value:—1. The Extraction by Casein of Trypsin Adsorbed by Charcoal, by Mr. S. G. Hedin. It is shown that casein is capable of extracting trypsin adsorbed by charcoal. This gives strong support to the view that the proteins combine with trypsin before they are broken up by the latter. 2. The Diastatic Ferment in the Tissues in Diabetes Mellitus, by Dr. F. A. Bainbridge and Dr. A. P. Beddard. Experimental evidence is given of the presence of a diastatic ferment in the liver and muscles of diabetic patients. In two cases a diastatic ferment was found in the blood and in two others it was absent. 3. An Improved Method for the Determination of Sugar in Blood and other Tissues, by Mr. E. S. Edie and Mr. D. Spence. The method consists in defibrinating the blood with aseptic precautions, dialysing with a measured quantity of 0.9 per cent. sodium chloride solution for about 45 hours in an ice-chamber, boiling the saline fluid, and adding an excess of Fehling's solution. The precipitated cuprous oxide is then washed, dried, ignited, and weighed as cupric oxide. By this method of determining the amount of sugar present

in blood evidence was obtained that the sugar exists in part as free sugar, in part in combination with protein or lecithin, the remainder being a polysaccharide or hydrolysible sugar. The serum alone contains sugar which was not found in the corpuscles. 4. A case of Specific Adsorption of Enzymes, by Mr. S. G. Hedin. It is shown that the α - and β -proteases in the spleen of the ox are adsorbed in the same proportions by charcoal, while kieselguhr adsorbs the α -protease more readily than the β -protease.

The Edinburgh Medical Journal.—The March number of this journal is of more than average interest. It opens with an address by Professor W. Osler on Cerebro-spinal Meningitis, in which some of the peculiarities of this disease are pointed out and reasons are given for deprecating any scare on the subject. The first Morison lecture (1907), by Dr. A. R. Urquhart, of which we have already published an abstract,¹ deals with insanity, with special reference to heredity and prognosis, and emphasises the dependence of mental states upon bodily conditions. Dr. F. H. A. Marshall and Dr. W. A. Jolly write on the influence of the ovary upon the uterus and conclude that the former gland supplies a "hormone" inducing menstruation and also some chemical substance necessary for the nourishment of the embryo in the early stages of pregnancy. Mr. B. G. A. Moynihan records some instructive cases of conditions in the large intestine simulating malignant disease.

The Scottish Medical and Surgical Journal.—Neurology is to the front in the original articles of the March number of this periodical. Dr. John Thomson and Dr. Stuart McDonald record two cases of meningococcal meningitis and suggest that attenuated meningococci may exist in the naso-pharynx of healthy children and be capable in certain circumstances of giving rise to virulent outbreaks. Dr. W. Elder and Dr. Nena Ievers give notes of five cases of the same disease in its epidemic form and state that some benefit seemed to be derived in two of these from injections of De Renzi's anti-pneumococcal serum. Mr. J. Hogarth Pringle writes on hæmorrhage from the sinuses of the dura mater and Mr. J. S. Fraser on perichondritis of the auricle following the radical mastoid operation.

The Quarterly Journal of Microscopical Science. Edited by E. RAY LANKESTER, F.R.S., with the cooperation of ADAM SEDGWICK, F.R.S., SYDNEY J. HICKSON, F.R.S., and E. A. MINCHIN, M.A. New Series, No. 201 (Vol. LI, Part 1), February, 1907. With lithographic plates and text figures. London: J. and A. Churchill. Price 10s. net.—The articles contained in this number of the journal are: 1. On the Parietal Sense Organs and Associated Structures in the New Zealand Lamprey (*Geotria Australis*), by Arthur Dendy, D.Sc., professor of zoology in King's College (University of London), with two plates. Dr. Dendy has had the opportunity of studying the anatomy of the brain of *geotria* in the "velasia" stage of development and describes with much minuteness of detail the pineal eye, or rather pineal eyes, for there is clear evidence of the existence of a pair, though differing greatly in histological characters and probably in function, the right pineal organ being either the most highly developed or the organ that has undergone least degeneration. This is a very interesting article and the illustrations are excellent. 2. Studies in Spicule Formation, by W. Woodland, demonstrator of zoology, King's College, London, Part 5, dealing with the scleroblastic development of the spicules in ophiuroidea and echinoidea and in the genera *antodon* and *synapta*. The article is illustrated by two plates. 3. In a second article, accompanied by a plate, Mr. Woodland describes the Scleroblastic Development of

the Spicules in some Mollusca and in one Genus of Colonial Ascidians. 4. In a third article Mr. Woodland enters into a preliminary consideration as to the possible factors concerned in the production of the various forms of spicules. 5. On *Neurosporidium Cephalodiscus n.g.n.sp.*, a Sporozoon from the Nervous System of *Cephalodiscus Nigricans*, by W. G. Ridewood, D.Sc., and H. B. Kantham, B.Sc., with two plates. 6. Gametogenesis and Fertilisation in *Nematus Ribesii*, by L. Doncaster, M.A., with a plate. 7. The Molluscan Radula, its Chemical Composition and Some Points in its Development, by Igerma B. J. Sollas, with a plate. 8. Observations on Tooth Development in *Ornithorhynchus*, by J. T. Wilson and J. P. Hill, with three plates.

New Inventions.

APPARATUS FOR ELEVATING THE HIPS IN BED.

Messrs. F. Davidson and Co., 29, Great Portland-street, London, W., have recently sent me a new apparatus for elevating the hips in bed which I feel sure will prove of the greatest value in all cases where the patient is very weak and helpless. I was in this condition myself about a year ago and one of the greatest troubles to me and to my nurses was the impossibility of preventing my slipping down the bed in consequence of the middle of the mattress under my hips sagging down to a lower level than that part of it under my shoulders. This trouble and discomfort I find is quite obviated by the use of the apparatus Messrs. Davidson and Co. have made for me. It consists of an oblong wooden frame, which is placed upon and across the bed. To that frame is attached another in such a

FIG. 1.

FIG. 2.

way that the side of it nearest the foot of the bed can be raised to any extent and there fixed. The space surrounded by this upper frame is filled in with spring wire, like that of a mattress, for the hips to rest upon. The lower frame has a strap and buckle upon each side, by which it can be attached to the upper posts of the bed which may often be found to require to be placed under the patient

so that one side of the upper frame comes just above the hips into the hollow of the back, the opposite one crossing under the raised thighs a little above the knees. (See Fig. 2.)
Tunbridge Wells.
EDWARD G. GILBERT, M.D. Durh.

A NEW ETHYL CHLORIDE INHALER. WITH IMPROVED ASEPTIC FACE-PIECE.

THERE are so many ethyl chloride inhalers that one hesitates before recommending another. Nevertheless, I believe there is still room for one, such as I suggest, which combines simplicity, efficiency, and reliability. As seen by the illustrations (Figs. 1 and 2) a tap which regulates the

FIG. 1.

FIG. 2.

administration of the anæsthetic is introduced between the face-piece and the bag. To charge the bag the tap is turned so that the indicator points to "Charge" and the ethyl chloride is injected through a small hole in the tap indicated at A in Fig. 1. The tap is then turned to "Air," thus securing the ethyl in the bag until quite ready to begin. With the tap in this position the face-piece is applied and the patient breathes air only which enters through the inlet seen in the side of the tap B in Fig. 1. At the beginning of an inspiration the tap is turned so that the indicator points to "Anæsthetic," as seen in Fig. 2. This movement closes the air inlet and opens the communication between the face-piece and the bag. This inhaler is specially convenient when a few minutes' continuous anæsthesia may be necessary, for without disturbing the face-piece air can be admitted to the patient, the anæsthetic can be shut off, and the bag can be recharged. The aseptic advantage of the improved face-piece will be evident. The face-piece being connected at its upper end instead of at its centre protects the other parts of the anæsthetic apparatus from contamination in the event of the patient spitting, coughing, or being sick. When desired the apparatus can be fitted to a Clover's inhaler.

The inhaler and face-piece have been made for me by Messrs. Rauschke, Limited, surgical instrument makers, Leeds.

ALEXANDER D. SHARP, M.D. Brux., F.R.C.S. Edin.,
Honorary Surgeon, Nose and Throat Department,
Leeds Public Dispensary.

BRISTOL GENERAL HOSPITAL.—The following scholarships have been awarded as follows: Clarke surgical scholarship (£15) to Mr. J. F. Blackett; Sanders scholarship (£22) to Mr. J. F. Blackett; Martyn Memorial scholarship (£10) to Mr. V. B. Green-Armytage; Henry Marshall prize (£11) to Mr. J. W. J. Willcox; and Lady Habersfield prize (£27) to Mr. W. J. Veale.

THE LANCET.

LONDON: SATURDAY, MARCH 23, 1907.

The Security of Tenure and Annual Reports of Medical Officers of Health.

PUBLIC health legislation, whether under this or any other Government, is liable to prove a somewhat halting process and it is only when the harvest of death garners its sheaves in very high places that any enthusiasm for preventive medicine is manifested. But even such enthusiasm is prone easily to be damped when a powerful deputation representing the trusts or trades likely to be affected prejudicially threatens with opposition the Minister more immediately concerned with the measure in question. It is needless to furnish illustrations of this invertebrate condition; they are daily before our eyes. But the regrettable part of this state of affairs is that this molluscos attitude obtains even with regard to matters concerning which Royal commissions or departmental committees have made unanimous reports and recommendations. It is generally conceded that so long as medical officers of health hold their appointments subject to the caprice of the local authorities, so long will such officers hesitate to make recommendations and to write reports which are likely to give offence to butchers, farmers, dairymen, jerry builders, or others who may happen to be members of these local authorities. An officer appointed annually, triennially, or quinquennially is not unlikely to hesitate before he, in effect, serves a nuisance notice upon his chairman, and equally the sanitary inspector may find it convenient to avoid the slaughter-houses, cowsheds, or insanitary property of members of his district council. In existing circumstances the medical officer of health is fortunate if his council can be prevailed upon to appoint him without any reference to the duration of his appointment and with a moiety of his salary paid out of the county funds with the concurrence of the Local Government Board. In cases such as these the position of the officer is reasonably secure, as he can only be removed with the consent of the central health authority. So far there is not a very large number of such appointments but we are glad to see that the town council of Rochester has recently shown its appreciation of the services of its medical officer of health by reappointing him without specifying any time limit.

In cases where medical officers of health are in general practice and devote only a part of their time to their official duties there may sometimes be advantages in the compulsory union of districts and the appointment of a whole-time officer, and, as was pointed out some years since by Mr. CHARLES E. PAGET, the county medical officer of Northamptonshire, it would be well to improve the machinery for effecting such combinations. Probably, however, some fundamental change will have to be made

if the greatest use is to be made of medical officers of health; and some rather drastic alterations, more particularly as regards rural districts, have recently been proposed by a select committee of the House of Commons which was appointed to consider the Housing of the Working Classes Amendment Bill which was, we believe, largely promoted by Dr. MACNAMARA, the present Parliamentary Secretary of the Local Government Board. The Bill in question aimed at facilitating the housing of the working classes in rural districts but the recommendations of the select committee take a much wider view of the whole problem than was contemplated by the Bill and it is clear that if such recommendations are accepted a new Bill will be called for. The committee furnishes as an appendix to its report several of the reports of medical inspectors of the Local Government Board dealing with the unsatisfactory arrangements which at present obtain in rural districts for the appointment of medical officers of health and sanitary inspectors, and much importance is attached to these reports by the committee; indeed, it would appear that such reports have formed very largely the basis of the conclusions arrived at. Although there are some ambiguous points in the report in question there is much that is useful and as a whole the document is commendably vigorous and independent. In so far as the medical officers of health and their annual reports are concerned, the committee considers that the indifference of rural district councils towards sanitation and housing is reflected in the lack of zeal or activity on the part of the officers. The memorandum of the Local Government Board relative to the annual reports of medical officers of health is, in the view of the committee, too indefinite and it suggests that where such reports indicate slackness or apathy more satisfactory reports should be insisted upon. Certainly, some of the reports of medical officers of health are of a very meagre nature, no mention being made of existing defects or of pressing sanitary requirements and too much being made of the fact that the death-rate is a low one or that the place is well suited for a health resort.

As regards Part III. of the Housing of the Working Classes Acts, the committee is of opinion that sanitary powers cannot be intrusted to comparatively small local bodies some of the members of which may be owners of cottage property or builders or agents having a direct interest in putting restraint on the administration of the existing laws. Consequently, it is recommended that the administration of the Public Health and Housing of the Working Classes Acts should be transferred from rural district councils to county councils, leaving to the rural district councils concurrent powers to build under Part III. of the Housing of the Working Classes Act, 1890, subject to confirmation by the Local Government Board. It is further advised that the appointment of a county medical officer or officers of health should be compulsory and that proper qualifications for such officers should be prescribed and insisted upon by the Local Government Board, this Board also issuing a more precise memorandum of instructions as regards annual reports and requiring strict compliance with them. It is not quite clear from the report whether these recommendations refer to county medical officers alone or to all medical officers of health, and indeed there is

much in the report which indicates some confusion of thought on the part of those who are responsible for it. They do not, for instance, appear to have appreciated the fact that the duties of county medical officers of health have not hitherto been prescribed by the Local Government Board. This and certain other points of doubtful meaning are probably due to the fact that very few medical officers of health were called to give evidence and that those medical inspectors of the Local Government Board whose reports have evidently much influenced the committee's decision were not apparently invited to attend. But all these details fade into insignificance before the fact that the committee has grasped to the full the importance of security of tenure and the improvement and independence of the annual reports of medical officers of health, and the fact is, no doubt, recognised that improvement of the reports is largely dependent upon security of tenure.

Pyorrhœa Alveolaris.

THE Erasmus Willson lecture on Pyorrhœa Alveolaris recently delivered by Mr. KENNETH W. GOADBY is a valuable addition to the knowledge of that refractory disease of the teeth.¹ Although early loss of the teeth accompanied by an inflammatory condition of the gums has been recognised since the days of AMBROSE PARÉ, it is only within recent years that the disease has become so prevalent that the attention of the general body of medical practitioners has been drawn to its far-reaching and harmful effects. In the lecture Mr. GOADBY mainly devoted his attention to giving a *résumé* of the bacteriological researches which he has made during the last ten years and to drawing attention to the use of the vaccine treatment on the lines advocated by Sir A. E. WRIGHT. In all 90 cases of the disease were examined bacteriologically, in addition to the various conditions such as gingivitis, ulcerative stomatitis, and so on; from these investigations very little evidence was obtained of any one organism occurring with sufficient regularity to suggest its causal relationship with the disease. The chief fact brought out seems to be that a very large variety of organisms is found in the gums in ulcerative conditions and that the bacteria found in gingivitis and ulcerative stomatitis show a very curious similarity to those found in pyorrhœa. Mr. GOADBY gives a very detailed bacteriological analysis of 36 cases in which certain general symptoms were present and describes the cultural characters of the organisms isolated. In certain cases he isolated a lactose-fermenting bacillus and this organism would seem to have suggested to him that the infection in pyorrhœa alveolaris may come from contaminated milk. In referring to this point he remarks: "McCONKEY has shown that these lactose-fermenting bacteria are primarily of faecal origin and that they gained access to milk, from which they had been isolated by him in a large number of instances. In attempting, therefore, to discover the original source of infection in alveolar pyorrhœa the presence of these lactose fermenters naturally requires consideration. Further, cocci of both the staphylococcal varieties are often present in milk and may exhibit some degree of virulence. In the absence

of any other obvious source of infection it would seem highly probable that the organisms to which at any rate the general symptoms attendant upon suppuration along the alveolar margin and at the alveolar process itself are due may come from contaminated milk." Mr. GOADBY also refers to the points that pyorrhœa alveolaris is a frequent sequela of infectious disease during which the patient has for some time been upon a milk diet and that the disease frequently occurs in several members of the same family and would seem to consider these points evidence that milk may be the original source of infection. The idea is certainly a novel one but we must confess that his evidence hardly seems to justify his suggestion. In the treatment of the disease he seems to have had some measure of success with the injection of vaccine of the different organisms and he brings forward certain facts which are of more than passing interest. He states that in curetting of even two or three sockets of affected teeth an increase of constitutional symptoms often takes place, and he considers that delayed healing is common and frequent when multiple extraction has been performed in cases of general pyorrhœa and as a precaution thinks it is inadvisable to remove more than two or three teeth at a single sitting. Most practitioners would, we imagine, dissent from this view but it is remarkable how facts easily apparent are often overlooked and it is certainly a question well worthy of attention. With the current idea that removal of the affected teeth arrests the local tissue destruction and cures the disease he does not altogether agree, and he cites a case where even after the removal of the teeth the patient lost weight, the opsonic index at the time of extraction being 0.6 and 0.5 respectively to the staphylococcus aureus and the mouth staphylococcus albus. At the end of one year the opsonic index was the same but as the result of inoculation during six months she gained 2 stones in weight, the index rose to 1.1, and chronic rheumatism from which she had suffered almost entirely disappeared. It would certainly appear that vaccine treatment may prove of some value but much more evidence and experience are necessary before anything like a definite opinion can be given. In reading through the paper we cannot help feeling that valuable a contribution as it is to the bacteriology and treatment of advanced conditions of alveolar destruction it sheds but little light upon the more important question of etiology. Why is the disease so prevalent at the present day? What are its true causes? These are the questions to be settled. The solution will probably be found by investigations carried on along lines quite other than the bacteriological.

The New French Lunacy Bill.

DURING the past half century the lunacy laws of most countries have undergone great changes. Nevertheless, up to the present time the French have adhered to the Act which came into force so long ago as June, 1838. When we consider the date of its enactment it may undoubtedly be looked upon as a very enlightened piece of legislation. But great changes have taken place since then and in most civilised countries the tendency has been more

¹ THE LANCET, March 9th, 1907, p. 633.

and more to protect the liberty of the subject; consequently in lunacy matters the public have long ago decided that they should be adequately protected against the risk of wrongful detention in an asylum. Bills have from time to time been considered by the French Senate or the Chamber of Deputies but for some reason or other they have all been abandoned. The law as it now stands permits a person to be sent to a lunatic asylum in two ways, (a) that which is known as the "placement volontaire," in which case the patient is detained under the order of a relative or friend, supported by one medical certificate; and (b) the "placement d'office," which is chiefly used in the case of violent or dangerous lunatics and is carried out on an order of a police commissary, a mayor or magistrate, supported by one medical certificate. Most persons will agree that such requirements are insufficient to insure the patient against hasty, if not wrongful, detention. Especial objection must be taken to the method known as "placement volontaire," for assuming that the person making the order directly or indirectly derives any benefit from the removal of his relative or friend to an asylum the certificate of one medical man can scarcely be regarded as sufficient guarantee that the case has been thoroughly considered, for it is possible that the physician may have been misled by false or exaggerated statements as to the conduct of the patient. It is true that in England to-day urgent private cases may be removed to a mental hospital under the order of a relative and one medical certificate but here it must be borne in mind that such an order only remains in force for seven days from its date, during which time further statutory papers have to be obtained, otherwise the patient must be at once liberated. In this country the methods of procedure vary according to whether the patient belongs to the private or pauper class, and by a pauper is meant any person who is unable to pay for treatment in private care, licensed house, mental hospital, or special paying wards in a borough or county asylum. The private patient can only be detained upon a reception order signed by a judicial authority, which order is granted upon the presentation of a petition and a statement which are signed whenever possible by a near relative and supported by two medical certificates.

In the case of pauper lunatics one certificate only is required, a justice of the peace making an order for detention after seeing the patient and being satisfied as to his insanity. Therefore in this country no person can be detained as a person of unsound mind unless his case has been considered by a judicial authority, whereas in France under the "placement volontaire" no such official consent is necessary. It is true that the director of any lunatic asylum, whether public or private, has within 24 hours of the patient being admitted to the establishment to furnish a certificate which is transmitted to the prefect stating that the patient is really insane, and 15 days later another certificate has to be furnished. In England the medical officer has to furnish to the Commissioners in Lunacy a medical certificate regarding the mental and bodily health of the patient not less than two clear days and not more than seven clear days after admission. This certificate is followed by another at

the expiration of one calendar month, and further the reception order has to be continued by means of certificates which have to be furnished at periodical intervals throughout the patient's residence under care, even if this extends to 40 or 50 years. In addition to these precautions patients are periodically visited by members of the Lunacy Commission, and in the case of private licensed houses in the country visits are also paid by justices of the peace who are specially appointed to make such inspections. In France a monthly official visit is paid by a member of the tribunal who is evidently an official without any special training and therefore cannot be looked upon as a competent judge as to whether a patient should be detained or granted his freedom.

If the new Bill which has recently passed the Chamber of Deputies becomes law the liberty of the subject will be more carefully protected. A judicial authority will have to be applied to before an order is made for detention in an asylum. The old medical certificate is replaced by a detailed medical report which has to be sent in to a magistrate, and this magistrate has the power of demanding an inquiry before the certificate takes effect. We think that it would be wiser both in the interests of the patient and the physician who certifies that in the case of private patients the law should require two medical certificates to be provided by independent medical men. This would insure the patient being seen by at least two physicians prior to his removal to an institution and in the event of any litigation for wrongful detention arising in the future there would be less likelihood of a verdict of negligence or malpractice being found. The certificate to be sent in at the end of 24 hours by the director of the asylum will be a much more detailed one than is the case at present and copies of it will be sent to both the procurator of the Republic of the district in which the asylum is situated and also to the corresponding official of the district whence the patient came. Fifteen days later another certificate has to be sent in to the same persons. It is not clear that either of these persons is capable of deciding the question as to whether a person is insane and a proper subject for detention in an asylum, and in any case such an authority cannot compare with our Lunacy Commission for competency. Finally, confinement in the asylum is not definitely decided upon until the president of the tribunal has agreed to it, after having thoroughly studied the different certificates which have been sent in. Further, if anybody lodges the smallest objection the president of the tribunal cannot come to a decision except after consulting with his court and having heard expert opinion. We do not believe that any such clauses will ever become law. Surely all this red tape cannot be required to protect the liberty of the subject and we further venture to think that such a law would be most prejudicial to the interests of the patient both from the curative and from the social standpoint, when we realise what publicity such inquiries must entail. The making of lunacy laws is always difficult but the day is past when legislators should give way to ignorant agitators. By all means let the person and the property of the insane be protected but let it also be borne in mind that there is another point of infinite importance, the recovery of the patient from his malady.

Thus in the endeavour to protect the patient neither should laws be made the working of which is vexatious to those who have the care of the insane, nor should they be so cumbersome as to prevent the possibility of early treatment.

Innotations.

"Me quki nimis."

THE DEATH OF M. BERTHELOT.

THE death of M. Berthelot, under painfully dramatic circumstances, following so closely upon that of M. Moissan creates a wide gap in the ranks of distinguished French chemists. The illness of his devoted wife had sorely affected the health of the great savant and the news of her sudden death proved to be such a shock to him that he never rallied and he entered the unknown practically in her company. M. and Madame Berthelot died in Paris on March 18th. Marcelin Pierre Eugène Berthelot was born in 1827 in Paris and was the son of a physician. His genius quickly showed itself in the early years of his education and his success in gaining a prize in an open competition on scientific subjects decided his career. At the age of 24 years he entered the Collège de France, in which he occupied the position of assistant to the lecturer on chemistry and thus his opportunities of gaining an insight into the teachings of chemical science widened. In spite of the number of great and fruitful investigations which he undertook with extraordinary energy and skill, he found time to serve the Government of his country. He was Minister of Public Instruction in 1885, four years after he had been elected a life senator, and in 1895 he was appointed Minister of Foreign Affairs. Berthelot's contributions to chemical science are known on account of their immense importance to the wide world over. He attacked the great problems of the constitution of matter with extraordinary energy and success. He laid the foundations of organic synthesis and was practically the founder of thermo-chemistry. Our knowledge of the chemical constitution of glycerine and the fats is largely due to Berthelot's keen insight and analytical acumen. He showed that the fats were natural glycerine ethers of various fatty acids. The outcome of these researches was a stimulus to the industry of glycerine making and the manufacture of stearine candles. The results of his beautiful investigations on this subject were embodied in a work entitled "*Sur les Combinaisons de la Glycérine avec les Acides*," a masterpiece of research which gained for him the admiration of the whole scientific world. In the same masterly manner he produced his comprehensive work, "*Chimie Organique fondée sur la Synthèse*" in 1880. In 1879 he published the fruits of his attack on thermo-chemical problems ("*Mécanique Chimique fondée sur la Thermo-chimie*"). Lastly, chemical literature was considerably enriched by the publication of his classical work "*Les Origines de l'Alchimie*." France and the whole scientific world have indeed lost a giant of research in the death of M. Berthelot; he has left a magnificent record of fruitful labour, he has gone before as a splendid example to those who are engaged in the earnest pursuit of the same momentous problems, and for years and years to come the results of his genius must shine forth.

THE IRISH UNIVERSITY QUESTION.

THE Irish University question bristles with as many points of dispute as does a sea urchin with prickles, and it is almost impossible to discuss it without entering upon regions of controversy where the medical man is an intruder. But

it is not difficult to see that the scheme of the late Chief Secretary cannot commend itself to scientific teachers and students. The scheme, it is understood, provides that Trinity College, Dublin, which is the university of Dublin, should be abolished and that a new university bearing the old name should be founded, including Trinity College; Queen's College, Cork; Queen's College, Belfast; and a new college for Roman Catholics in Dublin. Maynooth; Queen's College, Galway; and Magee College, Londonderry, were to be affiliated institutions. The present Royal University was also to be done away with and all its existing graduates were to be attached by Act of Parliament to the University of Dublin. This scheme, like most schemes which try to please everyone, pleases no one, so that the consolidation of forces aimed at by the scheme could be only consolidation in appearance. Trinity College is naturally unwilling to lose its ancient prestige and to become a mere college of a university created by Act of Parliament. The senate of the Royal University does not receive a death warrant with pleasure, the leaders of Roman Catholic opinion, both clerical and lay, condemn the scheme, and Lord Justice FitzGibbon in his refusal to accept it may be taken to express the opinion of a large section of non-Roman Catholics. Moreover, all the heads of the various colleges concerned object in the main, though here and there support is forthcoming. There is another scheme which finds some support—namely, that the University of Dublin should in future consist of two Colleges, Trinity College as at present, and the hypothetical New Roman Catholic College. But to this scheme both parties concerned object. The Roman Catholic hierarchy and many of the Roman Catholic laity are apparently willing to have their new College made an integral part of the existing Royal University. This is the scheme which was adopted in the minority report of the late Royal Commission and signed by Sir Edward Fry, Sir A. W. Rücker, and Mr. S. H. Butcher.

THE UNION OF THE LONDON MEDICAL SOCIETIES: THE POSITION OF THE MEDICAL SOCIETY OF LONDON.

As our readers know, the Medical Society of London has stood aloof from the combination of the London medical societies and reference was made to the matter by Mr. O. A. Ballance, the President of the Medical Society of London, in his speech at the recent festival dinner of the society. We regret that our necessarily brief note upon this dinner could not include fuller details of the speeches, but the following passage in Mr. Ballance's speech is of great interest at the present moment. "Perhaps it may be expected of me," said he, "that I should say something about the union of societies (of which many of us are members) which has recently taken place and which has been so much before us during the last two years. London is so vast that no one society and no union of societies can satisfy the whole wants of the profession. There must and ever will be many societies, but we the Medical Society of London wish the union of societies which has taken place a brilliant future and great prosperity. No one can doubt that union is a good thing and that it is better to pull together, rather than in isolation. I have already expressed the good wishes of the Medical Society to the union of societies. May I also express an earnest hope that we, the Medical Society of London, may be the recipients of the same kindly feelings, the same hearty sympathy, and the same friendly and generous acts from the union of societies as we have been accustomed to receive from each of the uniting societies before they became amalgamated into one great and powerful body. There are three societies of considerable antiquity in London which are all doing good work and whose membership is for the most part

made up of general practitioners. I refer to our own society, to the Hunterian Society, and the Harvelian Society. I should like to throw out the suggestion that in some way or other these societies might be affiliated together. They would still have to carry out their ordinary work separately and in different parts of London, but perhaps we might meet once a year altogether for some common object or purpose, and later perhaps we might become affiliated to the specialist and scientific societies which have united together and which will have their home in future at 20, Hanover-square." It will be seen that Mr. Ballance furnishes a reason for the absence of the Medical Society of London from the great coalition which has not been hitherto put forward—at least, we do not remember to have heard the argument before. We cannot help regretting, for our part, that this or other reasons prevailed with the Medical Society to the extent of preventing their adherence to the new amalgamation, but we are certain that all members of the new amalgamation, a large proportion of whom will rightly be general practitioners, will continue to wish good fortune to the Medical Society of London.

THE STANDARDISED SAUSAGE.

THE sausage is a common subject of jest since it is so often regarded as a convenient vehicle for materials which when undisguised certainly do not appeal to us as being suitable or even wholesome for the purposes of food. Whatever objectionable plan may have been practised in regard to the compounding of sausages in past times it seems probable now that on the whole sausages are made with wholesome ingredients, thanks to a careful system of inspection of our meat supplies. Though, however, the sausage may contain innocuous substances there can be little doubt that it affords opportunity for the perpetration of considerable fraud upon its patrons. This is not surprising when we find that there is absolutely no legal or authoritative definition of a sausage. The sausage that contains 90 per cent. of bread and 10 per cent. of meat is just as much a sausage as that which contains meat and bread in the inverse proportion. It is clearly, illogical and unfair to the purchaser that such should be the case. As a rule, the sausage is looked upon as supplying the place of meat and as a meaty and not farinaceous food, and doubtless it is bought with the idea that it supplies the same nutritious qualities as does meat itself. Moreover, the average price of sausages per pound is approximately that of the meat of which they are supposed to be made. When, therefore, the sausage contains, say, 75 per cent. of bread and the purchaser is charged from 8d. to 10d. or 1s. per pound for it, a very decided fraud is surely being perpetrated upon him. At all events, it will be agreed that bread is very dear which costs as much as 10d. or so per pound. Such a figure in point of fact represents about ten times as much as the value of bread at the present time. In our view this species of fraud is every whit as bad as putting a cheap substitute in butter or coffee and yet the practice continues unhindered and uncontrolled by any statute. Purchasers of the sausage are to be found largely amongst poor people and the fraud is practised probably for the most part in poor neighbourhoods. Generally speaking the tampering with the nourishing quality of food is bad enough but when the practice affects those who struggle most for a living, who find it hard to procure nourishing meals at all, it becomes monstrous. Surely it is time that the sausage should be standardised and that the selling of a commodity by that name should be an offence unless it is proved to contain a reasonable amount of meat. There is nothing to be said against a well-made sausage which is prepared with sound meat. On the

contrary, it affords a valuable, convenient, and appetising food, and that being so, the sausage should be standardised so as to prevent it from being loaded with a cheap substitute which is nearly always bread or broken and waste biscuits. We can see no difficulty about introducing such a desirable reform and abolishing a palpable fraud. The practice may not poison people but it certainly swindles them.

THE VIRTUES OF THE OLD APOTHECARIES.

THE medical profession is generally supposed to have been at a very low ebb in point of learning and disinterestedness during the middle years of the eighteenth century. It is instructive, therefore, to find an apothecary, who was also well known in literary circles in his day, taking up the cudgels in his colleagues' behalf. In his once much-admired work on the "Government of Children," published in 1753, James Nelson complains that, owing to the prevalent distrust of the medical profession, parents are unwilling to call in a practitioner when their children are ailing. The passage in which he defends the profession as a whole is curiously modern in tone and even in detail.

As for the calumnies, the sneers, and the misrepresentations of ignorant and designing people, such as apothecaries and physicians being in league together, and playing into one another's hands; the eleven-pence in the shilling; the cramming people with physic they do not want; and much more of the like nature; these are things that scarcely deserve any notice. I have now been full thirty years in the business; have seen and done far from an inconsiderable share; have attended with physicians of every rank, from those who first enter'd into practice up to those who have reach'd the summit; yet cannot charge either any single physician, or myself, with even an attempt to enter into an association to the prejudice of mankind. On the contrary, I have seen some who have laboured with disinterested zeal for their benefit; not merely because they could not have their fees, but because they would not take them. Were I cannot help observing how much the world is misled by appearances; because people see an apothecary with a good suit of cloaths on, they conclude he is above want; and because they see another in a chariot, they pronounce him rich; so too because a very few physicians make fortunes, they conclude that all the profession are wealthy. But how fallacious is all this! There is no profession, no trade in the kingdom, which we call genteel, that has so few rich men in it as the different branches of physic. Many a man in it, sensible that the world would have no opinion of his skill, if he appeared to disadvantage, keeps up a part with aching heart; many a chariot is in daily danger of breaking down; and many owe their stability more to their own parsimony, to their wives' portion, or some other fortunate event, than to the produce of their business.

SANITARY ADMINISTRATION IN PAIGNTON.

THE high standard of sanitation which some "health resorts" are accustomed to claim for themselves would not always be maintained were there not in each place a candid friend or an outspoken medical officer of health. Paignton enjoys the somewhat unusual position of possessing both in some degree. The candid friend tells us "that illness of various sorts seems to be epidemic" and alleges that cases of infectious illness are continually being heard of. Apparently, too, until quite recently illness and malaise were attributed to a sewer which leaked, and bathers encounter sewage near the shore under certain conditions of tide and wind. Isolation accommodation is said to be inadequate and owing to cases of enteric fever occupying the hospital cases of scarlet fever have to be left in their homes. Although it does not appear that the zymotic death-rate is a high one, a town such as this, with a population of some 9000, ought not to have such a prevalence of scarlet fever as is indicated by the notification returns, while as regards enteric fever its continued presence year by year is not a reassuring circumstance; nor ought a health resort of this character to have an infantile mortality of 125 per 1000 births. We are told also by a local critic that the water is unsafe to drink unless it is boiled but on the other hand it is alleged that such boiling is only called for in consequence of the hardness of the existing supply. Similarly the floating sewage is accounted for by the presence at times of the Channel fleet, the disposal of the

excrement of which is not under the control of the Paignton district council. As regards the disposal of refuse a destructor is said to be necessary—"urgently needed" are the words of the medical officer of health—while the action taken by the council in the matter of a new water scheme, which is to cost a large sum of money, is, the medical officer of health asserts, most unbusiness-like and attended with an air of mystery which he finds it difficult to understand. In his view the officials ought to know what is proposed to be done in the matter of water-supply to the various parts of the town. Then, again, the district councillors are apparently disregarding their own by-laws which provide that any road over 100 feet long must be 36 feet wide. The medical officer of health now tells us in his annual report that the district council is proposing to expend public money on making a road 600 feet long and 24 feet wide. Without additional knowledge we can express no further opinion than to endorse cordially the statement of the medical officer of health when he observes that "the work of your officials is difficult enough without its being possible for the public to turn upon us and say, your council itself does not carry out its own by-laws. If Paignton is to retain its good name as a first-class town this course of procedure must be stopped, or it will thereby bring self-government into disrespect and ridicule." In connexion with this statement and the attitude of medical officers of health generally we may draw attention to our leading article in the present issue on the security of tenure and annual reports of medical officers of health.

EARLY RUPTURE OF THE PREGNANT TUBE.

ON p. 805 of our present issue Dr. O. A. Scott Ridout has recorded a very interesting case of extra-uterine gestation which ruptured two days after the cessation of the last period. The patient, a young nullipara, had been married only two months previously and had been in excellent health, the only abnormal circumstance which she had noticed being that her last period had not continued for as many days as usual. On the morning of the second day after the cessation of this period she was seized with sudden collapse and the signs of internal hæmorrhage, and Dr. Ridout, on opening the abdomen, found an early tubal pregnancy situated in the isthmus of the left Fallopian tube which had ruptured into the abdominal cavity. The case is in many respects a typical example of the usual course pursued by this variety of tubal gestation. It is not unusual for a pregnancy in this portion of the tube to rupture within the first month of the date of conception and from the position of the ovum rupture of the tube is more common than tubal abortion, although tubal abortion in the majority of cases of tubal gestation is more frequently met with in the proportion of 4 to 1. Professor Taylor has pointed out that in many of these cases there is a condition of atrophy of the tubal wall and he is inclined to think that this is an important factor in causing the early rupture. Others have called attention to the same fact and whether it is associated with some atrophy of the tubal wall or not, at any rate most of the recorded cases of very early rupture are examples of isthmal pregnancies. One of the most remarkable cases of this kind is that recorded by Dr. Rumley Dawson,¹ in which on the fifteenth day from the certain date of insemination the tube ruptured. It is characteristic of such early cases that as a rule the tube ruptures without any apparent cause as happened in Dr. Ridout's case. Whether there is any atrophy present or not to explain the early rupture no doubt it is predisposed to by the fact that there is very little room for the development of the ovum in this portion of the tube and therefore

an early rupture of the gestation into the peritoneal cavity may naturally be expected. The large amount of bleeding which occurs when the minute size of the ovum is considered is astonishing. In the present case the small swelling found on opening the abdomen was only of the size of a hazel nut, and in a case recorded by Professor Howard Kelly in which the patient had not missed a period and bled to death, the swelling in the isthmal portion of the tube measured only one centimetre by two centimetres. In another case of the kind recorded by the same author in which the patient had gone two weeks over her time the little bluish mass in the tube measured only 1.5 centimetres in diameter, although two and a half litres of blood were removed from the abdominal cavity. The diagnosis of these dangerous cases is, as a rule, easy since there is no other condition except acute poisoning which will cause such dangerous symptoms of collapse in an otherwise healthy patient.

"SUNLESS MANCHESTER."

A CORRESPONDENT writes:—"Such is the heading of some communications to the Manchester papers respecting the gloomy overhanging pall of smoke so patiently tolerated by the long-suffering people, though it has a perpetually injurious influence on the life of both man and plant. This recognition of the evil springs up afresh from time to time and then after a while the 'smoke nuisance' seems to be forgotten again. Whether the recent revival of interest in the matter will lead to anything practical in the way of remedy cannot yet be told. Professor Weiss has spoken of the amount of light of which we are robbed by smoke and fog and of the difference found between the light in London and that at Torquay. 'It was like night as compared with day almost.' And as 'it [light] is an essential factor in the growth of plants everything must suffer in big towns like Manchester, not merely from fog, but under ordinary conditions.' Many years ago Mr. John Leigh, at that time medical officer of health of Manchester, drew attention to the sooty, tarry coating of the leaves of plants and to the choking of the stomata of the leaves in plants condemned to struggle for life in the Manchester of his day; and Professor Weiss says that the microscope shows each breathing pore to be filled with a little plug of black matter. But worse even than the diminution of light, due to the large quantity of carbon in suspension in the air, is the effect of the acid from the sulphur in the burnt coal, which, getting into the pores, attacks the tissue and causes the plant to shrivel up. A practical illustration of the presence of acid in the air can be obtained on any damp drizzly morning in the smarting of the eyes produced by the descending drops. Some ten or more years ago Dr. G. H. Bailey of the Victoria University made careful investigations as to the Manchester atmosphere and it is to some degree satisfactory that he does not think it is as bad now as it was then. The anti-smoke crusade was at first directed more against the various works in and around the town than to the grates and chimneys of private dwellings and at the time it was quite justifiable, for the numerous tall chimneys belched forth dense masses, rather than clouds, of black fuliginous smoke. Dr. Bailey thinks there is more enlightenment than there was among the city authorities, manufacturers, and others and that something has been done to improve the state of things and it must be acknowledged that black smoke from the tall chimneys is less in evidence than it used to be. It is now coming to be seen that 'the great trouble is from the miles and miles of small houses in such districts as Hulme,' from which the smoke does not get away but 'with a moist and heavy atmosphere it flows downwards.' Dr. Bailey found that some of the worst parts of Manchester for smoke at the ground level were the parts without factories,

¹ Transactions of the Obstetrical Society of London, vol. xi.

Professor E. Knecht has stated that one effect of smoke is not, perhaps, often considered—namely, the reduction of temperature. When travelling on the Continent he noticed in passing through one great manufacturing town an appreciable lowering of the temperature and that when they had passed beyond it there was a return of the warmth which they had experienced before. The absence of sunlight means also that its beneficial effects in the destruction of many pathological bacteria are also wanting, and though we cannot yet measure our loss in this respect, yet we know it must be great. Of the remedial measures Dr. Bailey would place careful stoking almost before the use of the various smoke-consuming contrivances which require constant intelligence in the using if their benefits are to be obtained. The cheapening of gas and its more extensive use for heating and cooking would also lessen visible smoke. That it might be cheapened when a profit of £50,000 goes to the relief of rates is evident, and this money would be more useful if devoted to lowering the price of gas for cooking and heating purposes and so lessening the production of smoke from private chimneys. Professor Weiss also suggests that the sanitary committee, in addition to the power of inspecting drains and closet fittings and of condemning the faulty ones, should, for the benefit of future tenants, have the power of compelling the builders to put in efficient grates. Mr. T. O. Horsfall has frequently drawn attention to the Arnott grate or stove as economical in the consumption of coal and effective in lessening the production of smoke. Unfortunately, however, it does not now seem to be made. At a meeting of the Manchester Association of Engineers held on March 9th the adoption of mechanical draughts in the firing of boilers was strongly advocated as securing the complete combustion of fuel and preventing the production of black smoke. One advantage would be welcomed by lovers of the picturesque as there would be no necessity for the erection of the lofty chimneys so disfiguring to the Lancashire landscape. Perhaps it may turn out that in the multitude of counsellors there may be safety and that some effective means may be devised for lessening the gloomy conditions under which the life of Manchester is carried on." We may point out that we have pleaded for such a desirable state of things in an annotation in THE LANCET of August 13th, 1904, under the heading of "The Passing of the Chimney."

THE DETECTION OF ACETONE IN THE URINE.

THE importance of a trustworthy test for acetone in urine is such that the improved modification of the sodium-nitroprusside reaction described in a note by Mr. Basil J. F. Jacksontaylor, published in another column, will be read with interest. Hitherto this test has depended upon the darkening which takes place on the addition of acetic acid to a solution of sodium nitroprusside, urine, and liquor potassæ. Mr. Jacksontaylor now suggests the substitution of strong ammonia for the liquor potassæ and the elimination of the use of acetic acid. Strong ammonia solution is accordingly added to a solution of sodium nitroprusside and urine. The strong ammonia solution if added carefully remains clear on the top of the fluid. "Should acetone be present, even in minute quantity, a well-marked and absolutely characteristic ring of magenta appears within from one to three minutes at the junction of the two fluids and gradually spreads upwards, pervading the whole of the ammonia solution if acetone is present in considerable amount." We have tried this test in THE LANCET Laboratory and find that it responds admirably. When carried out in the manner directed the test provides a simple and trustworthy method of diagnosing a urine containing acetone and is a decided advance on the tests hitherto employed. Strong ammonia solution keeps its place on the

top of the urine and the diffusion of purplish colour can readily be observed even when the amount of acetone present is small. We have received a pencil drawing showing the upward diffusion of the reaction but the test cannot be strikingly illustrated unless the drawing is coloured.

THE PAYMENT OF MEDICAL MEN UNDER THE MIDWIVES ACT.

At the last monthly meeting of the Rotherham corporation the following recommendation of the midwives committee was carried after considerable discussion:—

The committee recommend that the council agree to pay a fee of £1 1s. where a medical gentleman is called in, at the request of a midwife, in cases of flooding, convulsions, and rupture of the uterus upon the following terms and conditions—namely: These payments will be made contingent on a certificate and report being furnished by the medical attendant to the midwives' committee of facts within the knowledge of the medical practitioner which may appear to the authority necessary to the elucidation of the case. They will also be contingent on the carrying out by the medical practitioner at the earliest possible moment of any procedures arising out of the visit for which the sum of £1 1s. will be considered an inclusive charge. All cases, in fact, to be treated as cases of emergency by the medical practitioner called in. These payments will only be made in the foregoing circumstances where the income of the family does not exceed the following rate:—

Man and wife	...	...	...	21s. per week.
Parent or parents and 1 child	...	...	...	23s. "
Parent or parents and 2 children	...	...	...	25s. "
Parent or parents and 3 children	...	...	...	27s. "
Parent or parents and 4 children	...	...	...	29s. "
Parent or parents and 5 children	...	...	...	31s. 6d. "
Parent or parents and 6 children	...	...	...	33s. "
Parent or parents and 7 children	...	...	...	35s. "

The matter was brought before the corporation of Rotherham by the Rotherham and District Medical Guild and we congratulate the Guild, the borough, and Dr. Alfred Robinson, the medical officer of health, upon the decision. It is an obvious blot upon the Midwives Act that there is no provision for the payment of the medical services which in certain conditions it is compulsory upon the registered midwife to seek, and the corporation of Rotherham has made a progressive move in dealing with the point as it has done.

THE LOCAL GOVERNMENT BOARD AND PRECAUTIONS AGAINST CEREBRO-SPINAL FEVER.

As an outcome of the attention which is being given to epidemic cerebro-spinal meningitis and of the knowledge now obtained regarding the relation to this disease of Weichselbaum's meningococcus experimental work has lately been undertaken with a view to obtain a satisfactory serum for the prophylaxis or curative treatment of the disease. In particular a serum has been prepared by Professor W. Kolle from horses which have been rendered immune with cultures of the meningococcus. We are informed that the President of the Local Government Board has now authorised investigations to be made in the medical department of the Board with a view to ascertain whether the value of particular sera, especially for prophylactic purposes, can be determined by animal experiment, and whether any special mode of preparation is likely to increase the effectiveness of "anti-meningococcus" preparations of this kind. In view of threatened extensions of cerebro-spinal fever in the United Kingdom this inquiry is timely and the results obtained will be looked for with interest.

HISTOLOGY AND BACTERIOLOGY OF HUMAN AND BOVINE TUBERCULOSIS.

THE Royal Commission on Tuberculosis has just issued the first of the supplemental volumes which were promised in its second report. The volume in question is a report made to the Commission by Dr. Arthur Eastwood on comparative histological and bacteriological investigations of the relationship between human and bovine tuberculosis.¹ Dr. Eastwood

¹ London, Wyman and Sons, Fetter-lane; Edinburgh, Oliver and Boyd; Dublin, E. Ponsonby. Cd. 3378. Price 2s. 6d.

records and compares the nature of morbid processes set up experimentally by tubercle bacilli of human and bovine origin respectively, and also the cultural characters of bovine and human bacilli from a variety of different sources. The general result of his observations has led Dr. Eastwood, in reporting to the Commission, to emphasize the underlying unity of the morbid processes produced experimentally by infection with every variety of human and bovine tubercle bacillus. The Commission, in its second report, drew freely on Dr. Eastwood's observations, and the volume now issued illustrates the magnitude and thoroughness of the research which has been made into this aspect of the subject. We hope to revert later to some of the questions raised by this valuable report.

HEALTH STATISTICS OF THE PEABODY BUILDINGS.

THE forty-second annual report of the governors of the Peabody Donation Fund contains some most satisfactory statistics relating to the health condition during 1906 of the 19,737 residents of the buildings owned by the Trust. It is pointed out in the report that the birth-rate among the residents was equal to 30.5 per 1000, exceeding the general London rate by 3.8; that the death-rate did not exceed 12.5 per 1000 and was 3.2 below the mean rate in London; and that the rate of infant mortality was only 8.9 per 1000 births, against 133.0 in the whole of London. It appears that the buildings occupy nearly 33 acres in various parts of the metropolis and that the mean density of population on this area is equal to 603 persons per acre, or nearly ten times the mean density throughout London. The low death-rate of 12.5 per 1000, among a population with a mean density of 603 per acre, affords conclusive proof that a high proportion of persons to an acre is not necessarily dangerous to health. Tested by another standard it is clear that there is no overcrowding in the Peabody Buildings. The Census Commissioners in their report on the census in 1891 adopted as a standard of overcrowding any excess in ordinary tenements beyond two occupants per room. It appears from the Peabody report under notice that at the end of last year the governors of the trust had provided 12,323 rooms for the artisan and labouring poor of London, exclusive of bathrooms, laundries, and lavatories; as these rooms contained a population of 19,737 persons, the average number of persons per room did not exceed 1.6, well within the standard of overcrowding adopted by the Census Commissioners. The report states that the average weekly earnings of the head of each family in residence at the close of last year did not exceed £1 1s. 9d., showing that the residents are of a distinctly working-class character. That in a distinctly working-class population of nearly 20,000, for the most part residing in the north of London, the rate of infant mortality should be as low as 8.9 per 1000, affords striking testimony of the value of the Peabody Trust and should afford the greatest encouragement to those who are labouring to reduce the waste of infant life which is now the most unsatisfactory feature of English public health administration.

LESSONS IN THE MANAGEMENT OF INFANTS.

"I HAVE no hesitation in saying that in my opinion the proper time to teach girls about babies is from 10 to 13 years of age." These are the words of Mr. Benjamin Broadbent, the ex-mayor of Huddersfield, in his preface to a leaflet¹ by Mrs. Watson on the subject of the care of infants. This little publication of 12 pages has been prepared with a view to its being used in public elementary schools for the instruction of girls. It is written in the very

simplest language and contains quite enough information for the instruction of girls of this age. The first of the five lessons is devoted to the subject of baby's food, the second deals with the preparation of artificial foods, the third with washing and clothing, the fourth with sleep and fresh air, and the fifth with general hygienic rules, and the whole concludes with a list of questions which it is suggested should be put to the girls at the end of each lesson. In every respect this is an admirable little book, the advice given is quite sound, and the information is correct, while there is nothing in it to offend the most sensitive sense of delicacy, although, as Mr. Broadbent says, "it is a difficult matter to prepare girls for motherhood without endangering the freshness and sweetness of their innocence."

DISEASES OF THE URINARY ORGANS AT THE NECKER HOSPITAL.

A COMPLETE course of clinical demonstrations upon diseases of the urinary system will be held at the Necker Hospital, Paris, under Professor Albarran, commencing on April 18th. The course will last three months and will include about 60 lectures. The symptomatology and the diagnostic points of the various diseases will be lectured upon and illustrated by the exhibition of patients. Those attending the lectures will be given opportunities for the practical examination of patients as well as for instruction in the handling of cystoscopes and various other instruments used in the diagnosis and treatment of urinary disorders. Three lectures will be given per week in the Salle de la Terrasse, commencing at 2.30 P.M. During the first month those attending the courses will attend the consultations held every morning in the Salle de la Terrasse and during the two other months they will accompany Professor Albarran when he goes round the wards and at his demonstrations at the bedside. The number of those who can attend the class is limited. All information as to the conditions necessary to be observed for attending the classes can be obtained from Dr. Ertabischeff, chef de clinique of the Necker Hospital.

EIGHTH INTERNATIONAL CONFERENCE OF RED CROSS SOCIETIES.

WE understand, although no official information seems to have been given, that the Eighth International Conference of Red Cross Societies will be held in London from June 10th to 15th. We do not know who are responsible for the arrangements, but it has been said that their Majesties the King and Queen will receive the delegates at Windsor and amongst the entertainers will be the Marquis and Marchioness of Salisbury, Lord Rothschild, and others. It is believed that our guests will number about 200, and these will include some of the most distinguished men from all the continental States of Europe, America, Japan, &c. Several of these gentlemen will be accompanied by their wives and daughters. The Central British Red Cross Society has been dissolved and a new substitute is in course of organization. This is very much to be regretted, as we fear that the members of the older societies, many of which have existed for nearly 40 years, will change their opinion as to this being a practical nation. We once possessed a national society, but this has been swept away, and far more than a year attempts have been made to replace it, but hitherto without much result. The conference will afford an opportunity for us to learn something about the work in other countries, and we hope that a hall of sufficient space will be secured to enable some hundreds of persons interested in Red Cross work to attend the sittings of the congress and to learn something as to the manner in which it is regarded in other countries. This is

¹ Lessons on the Care of Infants, by Mrs. Watson. Copies may be obtained from Mr. B. Broadbent, Gateshead, Lindley, Huddersfield, at 1d. each, or 9d. per dozen.

a matter in which the whole Empire is concerned and the sooner the utmost publicity is given to the scope of the conference and the manner in which it is to be conducted the easier it will be to give satisfaction to our guests, not only socially but also in forwarding the objects for which they are coming to visit us. In connexion with the conference an exhibition of ambulance material is to be arranged and we should be glad to have some information as to this to place before our readers.

BILL FOR PASTEURISING ALL MILK SOLD IN NEW YORK CITY.

ACCORDING to the *New York Medical Record* of March 2nd a Bill providing for the pasteurisation of all milk sold in New York City has been introduced into the New York State Assembly. By the operation of the proposed measure the dealing in, and selling of, any milk in New York City which has not been pasteurised would bring upon the parties handling the milk imprisonment for not less than six months or a fine of £100 or both. It is provided by the Bill that the Commissioner of Health shall designate pasteurising stations at which every quart of milk taken into the city must be put through the process of pasteurisation and that the city must construct such stations. Following the process a stamp will be put upon the milk receptacle by the health authorities, whereupon the dairy and milk companies and any others whose milk has been subjected to the process may take their milk and deliver it. The Bill also makes provision for the confiscation and destruction of any milk found to be unpasteurised. Authority is also given for the appointment of a large number of additional milk inspectors. The Bill is very sweeping in its character and its introduction may be said to be due to the vigorous crusade in favour of pasteurising milk which has been carried on for some time by the lay journals of New York city.

EPIDEMIC CEREBRO-SPINAL FEVER.

CASES of cerebro-spinal fever continue to be reported from various localities, but there is no epidemic prevalence except in Glasgow and Belfast. On March 13th the medical officer of health of Chelsea reported to the borough council that a child in Ives-street, Chelsea, had been attacked by the disease and had been removed to a hospital. A fatal case has occurred at Little Corbey, midway between Brompton and Carlisle. Cases have also been reported at Tollesbury on the Essex coast, in Shropshire, and at Bolsover in Derbyshire. In Glasgow on March 15th there were 112 cases under observation as compared with 101 on March 8th; as mentioned in THE LANCET of March 16th, p. 763, the daily announcement of the cases notified and the deaths has been discontinued, but on March 18th the medical officer of health issued a statement showing that during the past fortnight there had been 93 cases and 55 deaths, as compared with 90 cases and 60 deaths in the preceding fortnight. There have been two fatal cases in Greenock, four in Kirkintilloch, one at Kilwinning, and one in the Olney district of Aberdeenshire. The Registrar-General's returns state that during February there were 140 deaths attributed to the disease in the eight principal towns of Scotland, being 66 more than in January. Of these 111 were registered in Glasgow, 13 in Edinburgh, 8 in Paisley, 5 in Leith, and 3 in Dundee. In Belfast the total number of cases notified up to the present time is 185, and there have been 104 deaths. In Dublin there has been no new case since March 6th; in all there have been 15 cases with 11 deaths, and on March 15th there were four patients under treatment.

THE Department of Public Health of Queensland, in a bulletin dated Feb. 2nd, states that 3 more cases

of plague have been notified since the date of the former bulletin, Jan. 26th. Case 16 was inadvertently omitted from the last bulletin and in proper sequence of cases from the New Farm area it should be numbered case 10a. The patient was a female, aged 14 years, coming from James-street, New Farm, and being a sister of patients Nos. 6 and 7 and a daughter of the patient No. 15. She was attacked on Jan. 25th with bubonic plague and is progressing favourably. The 3 cases admitted during the week—viz., 17, 18, and 19—were 3 males, aged respectively 49, 42, and 52 years. They were all attacked between Jan. 24th and 26th and were members of the cleansing gang working in the infected area. They were all employed in removing produce from Garnett's Store and probably contracted the disease from infected dust while engaged in cleansing. During the week two of the patients died. With regard to Port Douglas no further cases have occurred since the last bulletin. As regards the Mauritius a telegram from the Governor received at the Colonial Office on March 15th states that 1 case of plague was reported during the week ended March 14th, and there was 1 death from the disease.

H.R.H. Prince Christian, the Danish Minister, the Portuguese Minister, the Greek Minister, the Swedish Minister, the Archbishop of Canterbury, the Bishop of London, the Archbishop of Westminster, and the Chief Rabbi will support H.R.H. the Prince of Wales at a dinner, at which he has graciously consented to preside, to be held at the Hotel Cecil on May 14th in aid of the National Sanatorium for Workers Suffering from Tuberculosis. Mr. Alfred de Rothschild will kindly lend his hand for the occasion.

THE Queen has graciously intimated to the Lord Mayor that she will open "The Queen's Fête" in aid of cripple children at the Mansion House on Thursday, June 13th. Her Majesty has also consented to receive purses from children on the occasion in behalf of the fund.

THE King has been pleased to appoint Mr. William Henry Power, O.B., F.R.S., F.R.C.S., Medical Officer of the Local Government Board, to be chairman of the Royal Commission on Tuberculosis in the room of Sir Michael Foster, K.C.B., deceased.

THE Pirogoff Society of Russia is agitating for permission to call a pan-Russian congress of Russian medical men for May 8th next.

Dr. F. M. Sandwith has been elected lecturer in physics in Gresham College in succession to the late Dr. E. Symes-Thompson.

MILITARY MEDICAL VICTIMS TO THE PLAGUE IN CRONSTADT.—The *Novos Vremya* reports that on March 2nd Dr. Schreiber of the 11th Eastern Siberian Rifles attached to the Military Medical Academy, died from plague which he had contracted in the fort "Emperor Alexander I." at Cronstadt. His remains were incinerated and will be kept in an urn at the fort named. It has been found necessary to state that he was carefully nursed throughout his illness, the contrary having been reported in the press. Unfortunately, although it was hoped that the case was an isolated one, the information is now forthcoming that Dr. Podlevsky of the 3rd Caucasian Rifle Battalion, who was also attached to the Military Medical Academy and was engaged in the anti-plague serum laboratory in the fort named at Cronstadt, has been attacked by the same disease, presumably, says the above journal, whilst conducting the necropsy on the body of Dr. Schreiber. The latest intelligence from the fort is that Dr. Podlevsky is improving in health; his temperature was falling and he was fully conscious.

THE RÔLE OF THE BLOOD PLASMA IN DISEASE.

BY HARRY CAMPBELL, M.D., B.S. LOND., F.R.O.P. LOND.,
PHYSICIAN TO THE NORTH-WEST LONDON HOSPITAL AND TO THE
HOSPITAL FOR DISEASES OF THE NERVOUS SYSTEM,
WELBECK-STREET.

V.¹

In the last section we arrived at the conclusion that with the exception of genuine senile change disease never sets up spontaneously in a normally evolved cell. Indeed, we may go further and say that when disease arises in a cell it is, except in the case of genuine senile decay, almost always the result of noxious cell environment.

It is necessary here to attach a precise meaning to the term "cell disease." It has to be remembered in this connexion that the vital activities of the component cells of the organism fall under two heads and we may call them the egotistic and the altruistic. The primary concern of every cell is egotistic, the maintenance, namely, of its own vigorous vitality. Its secondary and, as it were, accidental function, is the altruistic one of administering to the needs of the organism as a whole, whether by controlling and coördinating its activities (neurons), by elaborating ferments and hormones or eliminating poisons (gland cells), or by providing for massive movement (muscle cells). It is true that it is for the most part in the discharge of their normal altruistic functions that the cells find the conditions most suitable to their individual health; but not necessarily so, for it may happen—and I would lay particular stress on this fact—that a cell may fall altruistically and yet maintain a vigorous egotistic life. This may not be the case with such a simple function as muscular contraction; it is probable that failure here necessarily implies some serious affection of the muscle cells, but the altruistic functions of the nerve and gland cells are of a much more subtle nature, and one can well understand how a group of neurons forming, say, a vaso-motor centre, might fail in properly regulating the calibre of the vessels which they control, or how, again, glands, such as those of the stomach, of the pancreas, or of the adrenals, might fail in elaborating their ferments and hormones in appropriate quality and quantity; one can well understand, I say, how such nerve and gland cells might fail altruistically and yet, individually considered, maintain a healthy and vigorous vitality. Nay, the very vigour of a cell may constitute an altruistic defect, as when the adrenals yield an excess of adrenalin and thus cause secondary evils (including very possibly atheroma); or when the gastric glands secrete a superabundance of hydrochloric acid, and so give rise to dyspepsia and the many evils which follow in its train; or, again, when in the primipara the mammary glands become from excess of activity unduly turgid, and thus set up pain and general nervous disturbance.

It is manifest, then, that a cell may gravely fail in some altruistic function and yet, individually considered, be perfectly healthy; only when the cell becomes the seat of actual degeneration (discoverable or not) and thus fails in vital activity, can it be said actually to be diseased. And I repeat that, with the exception of primary senile decay of the cell, disease as thus understood, rarely, if ever, affects the cell spontaneously (i.e., independently of some noxious influence operating upon it), certainly never if it be normally evolved. But though disease seldom or never occurs spontaneously in the cell, it often arises spontaneously in the organism. This arises from the fact that though spontaneous cell disease is rare, spontaneous failure in altruistic cell function is unfortunately common enough, and such failure is inconsistent with the health of the organism,² interfering, as it does, with that harmonious interaction between the various parts of the body which is necessary to health. Should the disturbance thus resulting be unaccompanied by gross organic change, the cells still preserving their individual health, it is spoken of as "functional"; it may, however, go on to gross organic change, and there is then actual disease (degeneration) of the

individual cells.³ We thus see how organic disease, involving actual disease of individual cells, may spontaneously break out in the organism, not through the spontaneous occurrence of actual disease in cells, but through a failure in their altruistic function, and one, moreover, which is perfectly consistent with their individual health; and in point of fact spontaneous organic disease, when not due to primary senile cell degeneration, practically always occurs in this way.

Altruistic cell defects may arise from defect in the constitution of the zygote, or they may be acquired as the result of external influences operating upon the organism to which the zygote gives rise. Only in the former case can the disease resulting from them be said strictly to be spontaneous, for only then can the external environment be wholly exonerated from a share in causation. The condition of the zygote giving rise to altruistic cell defect may be of the nature of a "genetic variation," arising, that is, *de novo*, and in this case the resulting disease would be innate, but not inherited; or it may be hereditary when the resulting disease would not merely be innate but inherited.

It was pointed out in Section I. that the gland cells take precedence of all others in determining the composition of the plasma and the nature of the metabolism in general, a fact which prepares us for the conclusion that it is largely through the gland cells that disease is inherited. Many individuals are from the very beginning of their career defectively endowed in respect of the gastric, pancreatic, adrenal, and other glandular structures. The gland cells in question may be endowed with a vigorous vitality and, individually considered, be perfectly healthy, though defective in one or other of their altruistic functions, and such defects may lead to actual defects in the organism. Where, however, disease results from altruistic cell defect it may not be possible, owing to the close interdependence of the various cells in the body, to say whether that defect is inherent in the gland cells or whether it has been secondarily induced in them through defect, innate or acquired, of some other cells. Sometimes, however, it is manifestly induced. Thus, in Addison's disease the defect of the adrenal glands is often due to tuberculous infection—i.e., to an external agent in the shape of a specific micro-organism. Again, the changes which take place in the thyroid and parathyroid glands in exophthalmic goitre are of a kind most unlikely to occur spontaneously in the individual gland cells; we may, indeed, regard it as certain that they are due to some specific environmental influence brought to bear upon them, probably through altruistic cell defect in some other part of the organism, and in so far as this disease is hereditary it is apparently due, not to any inherited weakness in the thyroid or parathyroid gland cells, but to the inheritance of a defect elsewhere.

The defect in the pancreatic cells on which pancreatic diabetes depends, though it might conceivably be inherent in them from the beginning, is probably always induced, for not only does the pancreas in this disease often show gross organic changes which are clearly not spontaneous, but the disease often begins quite suddenly, and it is well-nigh inconceivable that a multitude of independent cells should at one and the same time fail from purely spontaneous causes. This view does not, however, preclude the possibility of an inherent susceptibility to damage on the part of the affected pancreatic cells. In such a disorder as hyperchlorhydria the case for inherent gland defect appears strong, the fault here consisting in excessive vigour in respect of one particular function—i.e., the secretion of hydrochloric acid.

Perhaps even more potent than the glandular system to set up secondary disease and to transmit inherited disease through altruistic failure of its constituent cells is the nervous system, and there are many reasons why it should be. Not only can the nervous system directly control the activities of the muscle and gland cells which are anatomically connected with its efferent nerves, but it can indirectly control the activities of all the cells in the body through its influence on the composition and circulation of the plasma. Another reason is the extreme structural complexity and delicate organisation of nervous tissue, by virtue of which it is not only more liable than other tissues to structural defect,

¹ Articles I., II., III., and IV. were published in THE LANCET of Feb. 2nd (p. 313), 9th (p. 375), and 23rd (p. 635), and March 16th (p. 754), respectively.

² I am supposing that a sufficient number of cells are involved in the failure, otherwise there would be no appreciable effect upon the health

³ In a former section I spoke of disease as always involving some degree of cell dissolution, even though it is frequently so slight as to be undetectable. This referred to disease of the cell. It is, however, possible—theoretically at least—to get a functional disease of the organism, one involving simply a want of harmony in its activities, without any necessary cell dissolution. In most functional diseases, however, there is some undetectable cell dissolution.

but also more impressionable and more vulnerable. The degree of this structural complexity will be the better realised when it is remembered that the individual neurons are of all cells the most highly organised, and further, that the mutual arrangement of contiguous neurons is much more complicated than is that of the constituent cells of other tissues. In the case of such tissues as the muscular and the glandular this relationship is a matter of comparative indifference; contraction and secretion can be carried on quite satisfactorily by each muscle and gland cell independently of its relation to neighbouring muscle and gland cells. In the case of nerve centres, on the other hand, the mutual arrangement of individual neurons is a matter of the highest importance, since it is largely in virtue of the complex inter-relationship of its constituent neurons that the nervous system is able to carry on its controlling and coördinating functions, and it is chiefly also by reason of it that nervous tissue so greatly transcends all others in structural complexity.

The above considerations lead us to infer that many diseases usually regarded as wholly non-nervous in origin actually originate in the nervous system. Such a disease as idiopathic granular kidney affords a possible case in point: the renal degeneration in this affection is certainly brought about through the plasma, and as we have seen that the composition of the plasma is greatly under the control of the nervous system, who knows but the particular plasmic defect on which this affection depends may be traceable to the nervous system? It has also to be borne in mind that defect in one part of the nervous system may be responsible for disturbance in another part of it, and when the characteristic symptoms of the disease are due to this secondary disturbance, the part thus secondarily disturbed may erroneously be regarded as the one primarily at fault. On the other hand, there can be no doubt that spontaneous nervous diseases often do not originate in the nervous system at all, but result from spontaneous altruistic defect in some non-nervous tissue, especially in those engaged in elaborating the plasma, such as the digestive and hormone-forming organs. It is probable that many forms of nervous diathesis originate in this way, the nervous system being perfectly normal to begin with. Consider, for instance, the different effects on the nervous system of a hyper- and a hypo-active thyroid gland: the one gives rise to a restless, nervous, katabolic temperament; the other to one that is sluggish, apathetic, and anabolic.

The foregoing considerations point to the conclusion that spontaneous disease is of two kinds: that in which the cells of the organism become spontaneously diseased (= degenerated) and that in which spontaneous failure in altruistic cell function sets up secondary disease; and further, that with the exception of primary senile cell degeneration, spontaneous disease nearly always arises in the latter way. Indeed, it is difficult to be sure whether non-senile cell disease ever breaks out spontaneously. The most probable instances of its occurrence are afforded by such diseases as Friedreich's disease and the idiopathic muscle palsies, but even in these we cannot be sure that the degenerations characteristic of them break out spontaneously in the affected cells, and that they are not secondarily induced. If they are spontaneous we must confound that the affected cells have from the beginning of their career been abnormal, but no evidence of such abnormality is at present forthcoming; so far as is at present known the cells which become affected remain up to a certain period perfectly normal; at all events they appear for a time to discharge their functions normally, and this is the only available test of their normality. It is, however, conceivable, that they are from the very beginning defectively endowed; one can conceive, e.g., that in the idiopathic muscular palsies the affected fibres are defective in ferment-forming capacity,⁴ and that at a certain stage of their career this defect suddenly becomes emphasised. But if even in the case of such nerve degenerations in which the case for primary spontaneous degeneration appears strongest, we cannot with certainty postulate a spontaneous degeneration of the neurons, what shall we say of the other degenerative affections of the nervous system? I think we may safely conclude that, with the exception of primary senile degeneration of the neurons, they are all secondarily induced, as the result of noxious environmental agencies operating for the most part through the plasma.

Hence in all cases where there is actual disease of the individual cells, be they gland cells, muscle cells, neurons, or what not, we should suspect the operation on them of some noxious influence. This may be either plasmic or non-plasmic, the former playing much the larger part.

Constitutional disease.—When in a disease the blood plasma is disordered and this plasmic affection gives rise to any of the essential phenomena of the disease, we speak of it as a constitutional, or blood disease. In many cases of this kind—e.g., gout, tabes dorsalis, peripheral neuritis, the specific fevers, and all other recognisable bacterial disorders—we have no difficulty in recognising the disease as being essentially plasmic in nature; but if my conclusions as to the rarity of spontaneous cell disease be correct, and as to the wide rôle played by the plasma in inducing cell disease, it is obvious that there must be many diseases belonging to this category in which the plasmic origin is overlooked. Some of these I now propose to consider—namely, paralysis agitans, granular kidney, Graves's disease, myxedema, Addison's disease, acromegaly, diabetes, and insanity.

Paralysis agitans is generally looked upon as a primary affection of the nervous system. Although no definite nervous degeneration is found in association with this disease it is impossible to doubt that the nervous system is profoundly affected in it; and, indeed, no one can observe a series of these cases without convincing himself that he is dealing with a constitutional affection involving not only the nervous system but other tissues as well, and that all the essential phenomena of the disease are plasmically induced. Paralysis agitans is, in fact, a generalised symmetrical affection of a kind which could only be produced through the plasma. It is true that the characteristic tremor often begins hemiplegically, but this is only one among many symptoms of the disease, and even more constant than the tremor, and always in my experience antedating it, is the muscular rigidity, which is always symmetrical. Now are we to suppose that each of the countless cells, nervous and non-nervous, which are disordered in this disease, spontaneously and synchronously takes on morbid action? Or are we to suppose that a common noxious influence is brought to bear upon them, forcing them to disordered action? Surely the latter is the correct assumption. Now there is only one medium through which this common influence can act—i.e., the plasma.

I recently saw a case which is interesting in this connexion. The patient was said to be suffering from a nervous disease which had been variously diagnosed by various physicians. After her medical attendant had given me a brief description of the case I said to him, "I do not expect to be able to give the disease a name, but I have little doubt from what you have told me that it is essentially a plasmic disease, one in which the plasma is profoundly affected." The patient was a woman, aged about 50 years. She was sitting in the middle of a drawing-room, propped up in an invalid's chair. She did not stir as I entered the room but continued to gaze steadily in front of her; nor did she once turn her face when she spoke, and all her conversation was in slow measured tones. She was anæmic and emaciated and displayed considerable rigidity in the muscles of the neck and trunk and some also in the legs. She complained of pain in several joints, some of which were swollen, and of shooting pains in her extremities, with numbness and anesthesia in her hands and feet. There was no tremor. What was the diagnosis? I said to the medical attendant: "It is, as I anticipated, useless to attempt to give any one name to this disease. The central fact to bear in mind is that it is a plasmic disease. The blood is in a very bad way, for not only is it impoverished, as shown by the marked anæmia and emaciation, but poisoned, and probably also defective in respect of its hormonal constituents; we have in consequence to deal with a symptom-complex which may be described as a blend of several diseases in atypical form—to wit, hysteria, peripheral neuritis, rheumatoid arthritis, and paralysis agitans." The patient had, in point of fact, all these diseases. Now I venture to think that it would be impossible to grasp the real significance of such a case as this were the part played by the blood plasma in disease not kept clearly in view. And in connexion with this case I would recall the remark made in a previous section as to the utter impossibility of giving a special name to every case of disease which comes before us. In the case in question the plasma was defective in divers ways, and, as so frequently happens, the patient was afflicted with an illness which was a complex of many disorders.

⁴ I refer here to those muscle ferments which are needful to the normal nutrition of the muscle bio-plasma.

Here I would point out that it must not be supposed that because in any disease, nervous or other, the parts are not affected symmetrically the disease is not therefore of plasmic origin. It is true that all plasmically induced diseases, be they functional or organic, tend to be symmetrical, the plasmic poisons—when there is toxæmia—picking out the corresponding cells on each half of the body, but there is never complete symmetry; sometimes, indeed, there is decided asymmetry. This may be partly explained by the fact that the poison is not equally distributed to all parts of the body, but probably better by the fact that corresponding parts on the two sides are not necessarily identical in structure. I have myself seen uramic convulsions confined to one side of the body, and it is well known that the tremor of paralysis agitans, which (as I have sought to show) is a plasmic disease, generally starts hemiplegically, while differences in the involvement of the two sides of the body can practically always be made out in such unmistakably plasmically induced diseases as tabes dorsalis and peripheral neuritis. We must not, therefore, assume that because a disease is not strictly symmetrical it is not of plasmic origin. Not only may the two sides of the body not be symmetrically affected, but among a group of similar cells on one side some may be affected more than others: in progressive muscular atrophy, e.g., some of the neurons belonging to one particular muscle hold out much longer than others; indeed, of two adjacent neurons one may be apparently intact when the other is destroyed; in acute yellow atrophy, again, apparently healthy liver cells may be mixed up with the debris of dead ones, while even in advanced granular kidney some of the renal epithelia seem to be wholly unaffected.

Granular kidney affords an admirable instance of a disease in which the essential lesion (i.e., renal degeneration) and the chief clinical manifestations are produced through the plasma. There are no grounds for assuming that the renal degeneration which occurs in this disease is spontaneous. When the disease is caused by gout or lead poisoning it is acknowledged by all that the renal change is plasmically induced, and one would expect this also to be the case when it occurs idiopathically, as it may do, in those living under perfectly healthy conditions, and that, too, quite early in life. It is at least highly improbable that multitudes of independent renal cells should spontaneously begin to degenerate in exactly the same way at one and the same time; much more likely is it that even in these so-called idiopathic cases some noxious influence is at work on the renal cells. This influence must be either nervous or plasmic, and as there is no evidence that the characteristic renal changes can be brought about by the direct action of the nervous system, we must assume that they are produced through the plasma. Apparently the blood in this disease contains a substance which is destructive to the renal epithelium; we must assume that this nephrolysin results from some chronic metabolic disturbance in some tissue or tissues unknown, and that in this way the plasma is furnished with a constant supply of the poison, for granular kidney is always progressive—once started it continues with such fatal persistence to the end.

Just as the renal changes of granular kidney are plasmically induced, so also are the general manifestations of the disease—e.g., the high blood pressure, the cardio-vascular changes, the tendency to inflammations, and the not infrequent anæmia and cutaneous pigmentation. How far these effects are due to the primary plasmic defect which is responsible for the renal degeneration, how far to the retention in the blood of effete products consequent upon that degeneration, or how far to the absorption into it of broken-down renal epithelium, which is known to be capable of sending up the blood pressure,* we cannot say. One thing is, however, certain—i.e., that all the essential phenomena of the disease are produced through the blood plasma. It seems very doubtful whether failure in the excretory functions of the kidneys enters into the causation of the disease at all, except during the later stages, inasmuch as all its characteristic phenomena are observed long before the kidneys begin to show signs of failure.

As I have already hinted, aberrations of hormonal function probably figure largely in disease, though we as yet know but little concerning them. There are, however, certain well-defined diseases which can be more or less definitely traced

to disease in some hormone-producing tissue. Such are Graves's disease, myxœdema, Addison's disease, and acromegaly. In regard to myxœdema and Addison's disease, few will be prepared to deny a hormonal causation; there are some, however, who are less inclined to admit that the chief phenomena of Graves's disease are due to an altered state of the blood plasma consequent upon the faulty action of the thyroid or parathyroid glands; or, again, that the characteristic phenomena of acromegaly are secondary to disease of the pituitary body. But whatever view we may hold as to the exact pathology of these four diseases, there can be no doubt that their essential phenomena are produced through the plasma, inasmuch as there is no other medium capable of bringing them about. Myxœdema is now acknowledged by all to be a plasmic disease; but even if we had not practical evidence of the fact in the shape of a diseased or absent thyroid, and of the beneficial effect produced in this affection by administering thyroid extract, we might on *a priori* grounds safely infer its plasmic origin: only through the plasma could the generalised modification in nutrition characteristic of it be produced. Only through this medium, again, could the characteristic phenomena of Graves's disease—such as the rapid metabolism, the emaciation, sweating, pigmentation, and agitation—be produced. Addison's disease is so obviously an affection of the blood that there is hardly need to advance proof of the fact. The occurrence of pigmentation alone attests it, and it is manifest that the nutrition of the tissues generally is profoundly affected in this disease; moreover, the great fall in the blood pressure observed in it is just what one would expect to get in a disease having as a constant accompaniment degeneration of a tissue known to yield a powerful vaso-constrictor substance. Exactly the same arguments apply to acromegaly: only through the blood would it be possible for its characteristic anatomical changes to be set up. There is no medium other than the plasma capable of producing a widespread symmetrical overgrowth of osseous and fibrous tissue, and it is scarcely conceivable that some billions of cells should spontaneously take on this morbid form of activity. Apart from these considerations we have in acromegaly unmistakable evidence of blood alteration in the shape of pigmentation, sweating, and other cutaneous phenomena. The nutritive changes met with in this disease are, in fact, just as certainly plasmic in origin as are those which characterise puberty.

Diabetes is manifestly another plasmic affection: the plasma contains a superabundance of grape sugar. It is probable, however, that it is a plasmic affection in another sense, not merely, that is, in respect of the excess of sugar, but in the sense (in many cases at least) that some initial antecedent defect of the plasma is responsible for the hyperglycæmia. This conclusion can be arrived at *a priori*.

I have already advanced arguments in favour of the view that in pancreatic diabetes the disorder of the pancreatic cells which causes the diabetes is due to a noxious influence operating on them. This noxious influence almost certainly works through the plasma. But however the cells of the pancreas be disordered, it is evident that the disease of them can only cause diabetes in one way—i.e., through the plasma, by so altering its composition as to interfere with the normal metabolism of saccharide material. It is certain that the hyperglycæmia, whether secondary to the disease of the pancreas or some other organ, results from some peculiar condition of the plasma. In all cases of genuine diabetes there sooner or later comes a time when sugar is passed in the urine, even though all carbohydrates are omitted from the food, and, indeed, when food is withheld altogether. The sugar in such cases can only have one source—i.e., the tissues—and we must either assume that the plasma so influences these as to compel them to yield sugar in abnormally large quantities or that it is deficient in some substance needful for the utilisation of sugar; in other words, we are compelled to assume that the essential cause of diabetes lies within the plasma. I see no grounds for assuming, as some do, that the pathology of diabetes in the early phases of the disease, when the glycosuria can be eluded by withholding carbohydrates, is different from what it is in its later phases.³ It is essentially the same throughout. "We may conclude, in short, that genuine diabetes mellitus is from the beginning to the end of its course due to a faulty condition of the blood,

³ H. Batty Shaw has advanced evidence in favour of this view. He concludes that "kidney substance can alone be the cause of the rise of blood pressure met with in renal disease," Goulstonian Lecture III., THE LANCET, May 28th, 1906, p. 1461.

⁴ Pavy holds that the presence of sugar in the blood causes the protoplasm of the tissues to break down into sugar. "On Carbohydrate Metabolism," F. W. Pavy, M.D. Lond., LL.D., F.R.S. 1906.

leading to a faulty metabolism of sugar, and one can hardly doubt that this faulty blood state is due to defective metabolism of some tissue or tissues which normally yield to the blood something which is essential to the normal metabolism of sugar. During the early phases of the disease the specific blood defect is comparatively slight, so that the glycosuria can be held in check by curtailing the carbohydrate diet, but during the latter phases it is so pronounced that glycosuria occurs even during complete starvation." This passage in inverted commas was written in ignorance of the most recent expert opinion on the physiology of sugar metabolism and was arrived at deductively. It was therefore with great interest that I read the latest pronouncement on the subject by an accomplished physiologist: "The primary cause of the accumulation of sugar in the blood in pancreatic diabetes is the withdrawal from the blood of some internal secretion yielded by the pancreas necessary for the utilisation of dextrose,"* and later the same authority adds that there can be no doubt "that a want of destruction of dextrose must be the cause of the glycosuria." Pavy, on the other hand, attributes pancreatic diabetes to the absence from the plasma of something needful for the assimilation rather than for the destruction of carbohydrate.[†] It will, however, be observed that on either view pancreatic diabetes results from a plasmic defect.

We have seen that all the characteristic symptoms of insanity can be produced by certain substances (such as drugs and bacterial poisons) operating through the plasma; and also that alterations in the hormonal constituents of the plasma (such as happen, e.g., in Graves's disease) may cause virulent "nervousness." Facts such as these prepare us for the conclusion that insanity may be plasmically induced; and there is unmistakable evidence that this is actually the case. Thus insanity is known to be sometimes caused by chronic alcoholism, and by the specific fevers, in which cases the essential cause obviously operates through the blood; and there can be no doubt that many other forms of mental disease are similarly induced. Indeed, it is probable that most cases of insanity, other than those due to such causes as trauma, some cases of tumour, and primary senile degeneration, are essentially plasmic in origin.

We are compelled to assume that with the exception of cases of this kind the plasma takes some part in the causation of all those cases of insanity in which gross structural changes are met with in the cerebral neurons; for on the principle already laid down such changes must be due to some noxious influence operating upon the affected neurons, and nervous influence being incompetent to bring them about we can only conclude that they are produced through the plasma.

When pronounced structural changes have taken place in the brain complete recovery from insanity is impossible; but in the absence of such changes there may be complete recovery. As in the former cases, so in the latter, we must assume the existence of a noxious environment operating upon the disordered neurons, for we may lay it down as an axiom that *spontaneous disorder and spontaneous recovery of a cell are incompatible*. Such an occurrence would imply an inherent tendency on the part of the disordered cell spontaneously to deviate from the normal at a certain point in its vital cycle and at a later period spontaneously to recover—an assumption for which there is no kind of warrant. Recovery from a disease is *ipso facto* proof that the disordered state of the cells responsible for it has been induced in them through their environment.

The noxious influences which may so disturb the cerebral neurons as to cause insanity may be either plasmic or non-plasmic, or a combination of both; but as a matter of fact all the non-plasmic causes, other than tumour and trauma, operate chiefly and essentially through the plasma. Among them may be mentioned mental causes (e.g., excitement, suspense, fear, and excessive intellectual effort), and such reflex causes as eye-strain. Now all the mental causes mentioned lead to marked plasmic alteration, upsetting as they do digestion and the functions of internal secretion and excretion; they may, indeed, modify the composition of the plasma and the metabolism of the entire organism in an incredibly short space of time; fear, for instance, may in a few moments lead to a perceptible change in the odour of the sweat and breath. The reflex causes of insanity probably also act largely by influencing the plasmic environment

of the cortical neurons. Thus, when severe eye-strain is the starting point, as it actually may be, it probably acts chiefly by disturbing the general health and thus modifying the composition of the plasma; it may conceivably act also by reflexly causing vaso-motor disturbance of the brain, and in this way interfering with the proper circulation of the plasma.

We thus see that the blood plasma plays a preponderating part in the causation of insanity; and it is probable that when there is an innate tendency to this affection, it is rather because of an innate tendency for the plasma to become disordered in a way calculated to set it up, than because of an innate tendency on the part of the cortical neurons to become spontaneously disordered. In suggesting this I am not denying that the cerebral organisation may be such as to predispose to insanity.

Doubtless many of the plasmic changes which take place in chronic insanity develop in the course of the disease and are not responsible for the primary outbreak, though necessarily adding their quota to the clinical picture of the disease. Such plasmic changes result inevitably from the constant action and reaction taking place between the blood and the tissues. There can, however, be little doubt that in most cases of insanity the blood is from the very beginning of the disease specifically altered, and that this specific blood state is its essential cause. It is probable that the most sane individual would become insane if his brain were constantly fed with the blood of a chronic lunatic, and not only so, but that he would suffer from the same kind of insanity; just as, contrariwise, it is probable that in most cases of insanity without serious brain disorganisation the constant feeding of the brain with healthy blood would effectually re-establish the normal mental balance.

Summary.—The functions of the component cells of the organism may be considered from the egoistic and the altruistic standpoint, and it is possible for a cell to fall altruistically and yet possess a vigorous vitality, and thus, considered individually, be free of disease; a cell cannot be said to be actually diseased unless it degenerates and falls in vitality. Cell disease as thus defined rarely occurs spontaneously in the cell. Spontaneous disease in the organism is, however, quite common and, when it occurs, generally results from altruistic failure in cell function, interfering with the normal harmonious interaction between the various parts of the body, and thus causing functional or even organic disease.

(To be continued.)

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

AN ordinary meeting of the Council was held on March 14th, Mr. HENRY MORRIS, the President, being in the chair.

Mr. J. Ernest Lane was introduced and having made a declaration in the terms of the oath prescribed by the Charter of 1800 was admitted a member of the Court of Examiners.

The PRESIDENT reported the death on Feb. 19th of the Hon. Sir William Hales Hingston, M.D., LL.D., D.O.L., of Montreal, an honorary Fellow of the College, and he stated that he had written to Lady Hingston to express the sympathy and condolences of the Council.

The PRESIDENT reported the delivery of the Erasmus Wilson lectures by Mr. Willmott H. Evans, Mr. Reginald Cheyne Elmslie, and Mr. Kenneth W. Goadby. He also reported the delivery of the Hunterian oration by Mr. Henry T. Butlin. The best thanks of the Council were given to Mr. Butlin for his oration and he was requested to publish it. The President also reported the delivery of the Arris and Gale lectures by Mr. J. F. Dobson and Dr. Bertram L. Abrahams. The President further reported the delivery of the Hunterian lectures by Mr. W. Sampson Handley, Mr. J. W. Thomson Walker, and Mr. J. Howell Evans. The President reported that Mr. William Wright's Hunterian lectures had been unavoidably postponed owing to his illness.

The PRESIDENT stated that in pursuance of the Bradshaw bequest he had chosen Mr. Bickman J. Godlee as Bradshaw lecturer for the ensuing collegiate year.

Sir Gilbert Blane's medals were awarded to Staff Surgeon James William Wilcocks Stanton, R.N., for his journal of

* Recent Advances in Physiology, &c. Edited by Leonard Hill. Pp. 312-334.

† Op. cit., pp. 70 et seq.

H.M.S. *Suffolk*, 1905, and to Surgeon Bernard Ley, R.N., for his journal of H.M.S. *Algerine*, 1904.

Mr. A. Pearce Gould was re-elected as representative of the College upon the Senate of the University of London.

Dr. J. Ward Cousins was re-elected as representative of the College on the Central Midwives Board.

It was announced that a letter had been received from the secretary of the London School of Medicine for Women, inclosing a list of 2708 signatures in support of the petition to the Council in favour of the admission of women to the examinations of the College.

A letter was read from Dr. Arthur Keith reporting his attendance as the representative of the College with the deputation to the Prime Minister to urge the importance of a national anthropometric survey, and giving a short account of the grounds upon which the importance of this survey was urged and of the reply of the Prime Minister. A vote of thanks was accorded to Dr. Keith for his services as the representative of the College.

Looking Back.

FROM

THE LANCET, SATURDAY, March 21st, 1829.

YELLOW FEVER AT GIBRALTAR.

This formidable epidemic has at last ceased to rage; and, since the 16th of January, it has been deemed unnecessary to enforce any longer the quarantine, and the other sanitary measures. The number of patients who were affected with the yellow fever, amounts to 5,270, to which, it appears, no less than 1300 must be added, who were not entered in the official accounts; 1412 of the above number were soldiers, and amongst them the mortality was 1 to 3.41; amongst other patients, it was only 1 to 4.15; the absolute number of deaths was 1658.

M. Chervin, whose researches on the nature of yellow fever have been given in a former number of THE LANCET, was sent by the Académie Royale de Médecine of Paris to Gibraltar, in order to observe the epidemic. In his last communication to the Académie, he declares the disease at Gibraltar to be identical with the yellow fever of the West Indies; and asserts, that the most scrupulous investigations he made, during his stay at Gibraltar, with respect to the contagiousity or non-contagiousity of the disease, have only contributed to confirm his former opinion on the subject. M. Chervin was accompanied by M. Louis, who, soon after his arrival at Gibraltar, had a slight attack of the disease, from which he recovered within a short time. As soon as the official report of MM. Chervin and Louis has been laid before the Académie Royale, an extract of it shall be given to our readers.

SUBSTITUTE FOR HOPS.*

To the Editor of THE LANCET.

SIR,—In THE LANCET, No. 287, (Feb. 28, 1829,) it is stated that Mr. Yosy made a communication to the Medico-Botanical Society, respecting the use of the common buckbean, or marsh-trefoll, as a substitute for hops, and for which they presented him with their silver medal. I can attest as to its proving an excellent succedaneum in this respect; for, about the year 1820, when hops were at an exceedingly high price, I prepared a considerable quantity of extract from the plant, of which I sold a great deal.

If I be correct in my remembrance, a small pill box full, containing nearly two drachms, was considered equal to one pound of hops. What tends, in some degree, to establish the approval of the article in the process of brewing is, that they were private householders only who purchased it.

I am, Sir,

Your obedient servant,

L. TOWNE.

March 10, 1829.

* Vide "Looking Back" in THE LANCET of March 2nd, 1907.

Public Health and Poor Law.

LOCAL GOVERNMENT BOARD.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

Guildford Borough.—The town council has built 18 cottages which are now let at from 6s. 8d. to 7s. 6d. weekly, the total cost of such cottages having been £4266. Dr. R. W. C. Pierce states that it has not been found possible to build cottages to let at about 5s. weekly, the maximum amount which a labourer can afford to pay, and thus, he adds, the housing problem has not yet been solved. The larger of the cottages referred to above have each a living room, kitchen, scullery, and three bedrooms; in the smaller the kitchen is omitted. Dr. Pierce does not discuss the important question as to the percentage which a town council trading in houses may reasonably expect to obtain, but it would not appear that a weekly rental of £6 5s. for 18 cottages which cost £4266 is altogether a bad return. The council decided to allow a letter from the Kingston guardians asking the council to petition the Local Government Board to make pulmonary tuberculosis notifiable in a compulsory sense to lie on the table.

Guildford Rural District.—Steps were taken by the medical officer of health of this district in 1906 to prevent the overcrowding of cottages by London holiday children and by means of a circular sent to persons responsible for the despatch of the children it was urged that all should be carefully examined before leaving London and that pains should be taken to insure that they could be provided with at least 300 cubic feet of space in the cottages to which they were going. During the summer two cases of scarlet fever occurred amongst gipsies who were fruit-picking, these gipsies visiting the neighbourhood for strawberry and raspberry gathering. Apparently the custom obtained locally some years ago of commencing the summer holidays at an earlier period in order that both parents and children might do the work. Dr. Pierce thinks that this arrangement was a good one in that it enabled the local people to obtain healthy employment and also prevented the introduction of undesirable labourers.

Maldon Rural District Council.—The housing problem in rural districts is of such interest that any details relative thereto are helpful even when they record nothing but financial failures. Dr. J. O. Thresh tells us that Mr. Fels, whose name is so honourably associated with attempts to deal with the housing problem, has purchased a farm in this district and divided it into holdings of from five to ten acres each. 26 houses are to be built and 14 of them are already occupied, there being in connexion with the cottages a range of glass-houses for the use of the tenants. Apparently the rent for each holding is about £24 per annum. The experiment, which was, it appears, carried out by the district council at Bradwell, has not been altogether a brilliant success. The six cottages which were erected in 1904 cost £1450, and the annual payments amount to £81 2s. 9d. in connexion with repayment of the loan and £14 13s. for rates and repairs. As the rents only amount to £54 12s. there is a deficit of £41 3s. 9d. to be met by the rates, and this amounts to 2½d. in the £.

Chelmsford Rural District.—A somewhat startling outbreak of arsenical poisoning occurred in this district during 1906 and it illustrates a method of poisoning by this drug which was not contemplated by the Royal Commission on Arsenical Poisoning. A publican supplied beer to a purchaser in a gallon stoneware bottle and on the same day five persons who partook of such beer were attacked with sickness, diarrhoea, and abdominal pain in from ten minutes to two hours afterwards. On the following day those who had consumed some of the beer and then suffered gave the remainder, apparently with no criminal intent, to a neighbour, and three persons who drank it were taken ill afterwards. On examining the bottle Dr. Thresh found, he states, the lower part and bottom thickly encrusted with crystals of white arsenic, and this notwithstanding the fact that the landlord had scalded the bottle before using it. In the half-pint of beer which was left in the bottle when Dr. Thresh broke it there were found 30 grains of arsenic in solution. It is added that the beer when taken on the first day must have contained about four grains of arsenic to the

pint, and, on the second day, as much as ten grains. In these circumstances it is, indeed, very remarkable that no fatal results ensued, as each person, we are told, had one or two glasses.

Taunton Urban District.—Dr. H. J. Alford reports that through the generosity of three local residents three beds at the Winsley Sanatorium for Consumption have been placed at the disposal of the town. This sanatorium was erected for the use of the three counties of Somersetshire, Gloucestershire, and Wiltshire, and a large number of the beds, including, we believe, 20 by the town council of Bristol, have been subsidised.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN 76 of the largest English towns 8507 births and 5478 deaths were registered during the week ending March 16th. The annual rate of mortality, which had been equal to 18.4 and 18.2 per 1000 in the two preceding weeks, further declined to 17.8 in the week under notice. During the first 11 weeks of the current quarter the death-rate in these towns averaged 19.3 per 1000, the rate during the same period in London being 19.6. The lowest death-rates in the 76 towns during the week were 6.4 in Hornsey, 8.8 in Burton-on-Trent, 10.7 in Coventry, and 11.0 in Northampton; the rates in the other towns ranged upwards to 23.4 in Sunderland, 23.8 in Birkenhead, 24.2 in Huddersfield, and 26.5 in Plymouth. The 5478 deaths in the 76 towns showed a further decline of 129 from the numbers returned in the two previous weeks, and included 485 which were referred to the principal epidemic diseases, against 440 and 470 in the two preceding weeks; of these, 199 resulted from measles, 114 from whooping-cough, 60 from diphtheria, 39 from diarrhoea, 24 from scarlet fever, 19 from "fever" (principally enteric), and not one from small-pox. The deaths from these epidemic diseases were equal to an annual rate of 1.5 per 1000 in the 76 towns, the rate from the same diseases being also 1.5 in London. No death from any of these epidemic diseases was registered in Plymouth, Southampton, Halifax, Swansea, or in 12 other of the 76 towns; the annual rate therefrom, however, ranged upwards to 5.3 per 1000 in Portsmouth and Birkenhead, 7.0 in Hanley, and 8.5 in St. Helens. The 199 fatal cases of measles showed a slight decline from the number in the previous week, but caused an annual rate of 4.3 in Portsmouth, 4.4 in Birkenhead, 4.5 in West Bromwich, and 6.8 in St. Helens. The 114 deaths from whooping-cough showed an increase, the highest annual rates therefrom being 1.2 in Nottingham and in Rhondda, and 1.3 in Tottenham. The 60 deaths referred to diphtheria were fewer by nine than those in the previous week, but showed a considerable proportional excess in Hanley and Barrow-in-Furness. The three deaths from scarlet fever in Hanley were equal to an annual rate of 2.3. The deaths from "fever" were considerably below the average; one death of a child was referred to cerebro-spinal fever in London. No case of small-pox has been under treatment in the Metropolitan Asylums Hospitals since the end of June last. The number of scarlet fever patients under treatment in the Metropolitan Asylums Hospitals and in the London Fever Hospital, which had steadily declined in the 11 preceding weeks from 3848 to 2378, further fell to 2326 in the week under notice; 327 new cases of this disease were, however, admitted to these hospitals during the week, against 326 and 306 in the two previous weeks. The deaths in London referred to pneumonia and other diseases of the respiratory organs, which had been 432 and 405 in the two preceding weeks, further declined to 403 in the week under notice, but exceeded the corrected average number in the corresponding week of the last five years by 35. The 26 deaths referred to influenza in London were eight below the corrected average. The causes of 62, or 1.1 per cent., of the deaths registered during the week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in London, Leeds, West Ham, Nottingham, Salford, Leicester, and in 49 other of the 76 towns; the proportion of uncertified deaths, however, again showed a marked excess in Liverpool, Birmingham, Preston, Sunderland, and South Shields.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in eight of the principal

Scotch towns, which had been equal to 20.3 and 20.6 in the two preceding weeks, declined again to 20.5 in the week ending March 16th, but exceeded the mean rate in the 76 English towns by 1.9. The rates in the eight Scotch towns ranged from 13.2 and 17.9 in Dundee and Aberdeen to 21.0 in Perth and 23.5 in Glasgow. The 712 deaths in the eight towns showed a decline of four from the number in the previous week, and included 100 which were referred to the principal epidemic diseases, against 98 and 112 in the two preceding weeks. These 100 deaths were equal to an annual rate of 2.9 per 1000, which exceeded by 1.4 the rate from the same diseases in the 76 English towns; they included 43 which were referred to "fever," 33 to whooping-cough, 13 to diarrhoea, six to measles, four to diphtheria, one to scarlet fever, and not one to small-pox. The deaths referred to "fever," which had been 47 and 52 in the two previous weeks, declined last week to 43, and included 35 in Glasgow, two each in Edinburgh, Leith, and Greenock, and one each in Aberdeen and Paisley; 33 of the 35 deaths from "fever" in Glasgow, and all those recorded in Edinburgh, Leith, Greenock, and Paisley, were certified as cerebro-spinal meningitis. The 33 fatal cases of whooping-cough, showed a further increase upon recent weekly numbers, and included 22 in Glasgow, four in Aberdeen, four in Greenock, and three in Edinburgh. Nine of the 13 deaths attributed to diarrhoea occurred in Glasgow and two in Edinburgh. Of the four fatal cases of diphtheria, three were returned in Glasgow; and four of the six deaths from measles in Edinburgh. The deaths in the eight towns referred to diseases of the respiratory organs, including pneumonia, which had been 124 and 149 in the two preceding weeks, further rose to 155 in the week under notice, and exceeded the number in the corresponding week of last year by 32. The causes of 29, or 4.1 per cent., of the deaths registered in the eight towns during the week were not certified or not stated; the percentage of uncertified deaths in the 76 English towns during the same week did not exceed 1.1.

HEALTH OF DUBLIN.

The annual death-rate in Dublin, which had been equal 23.6 and 25.2 per 1000 in the two preceding weeks, further declined to 24.9 in the week ending March 16th. During the first 11 weeks of the current quarter the death-rate in the city averaged 28.0 per 1000; the mean rate during the same period did not exceed 19.6 in London and 19.9 in Edinburgh. The 187 deaths of Dublin residents registered during the week under notice showed a further decline of two from the numbers in recent weeks, and included 18 which were referred to the principal epidemic diseases, against nine and ten in the two previous weeks. These 18 deaths were equal to an annual rate of 2.1 per 1000, and included five from whooping-cough, four from measles, four from diarrhoea, one each from scarlet fever, diphtheria, and "fever," and not one from small-pox. The fatal cases of whooping-cough showed a decline, while those of measles exceeded the numbers in recent weeks. One death was also referred to cerebro-spinal fever. The deaths in the city included 39 of infants under one year of age and 52 of persons aged upwards of 60 years, showing an increase upon the numbers in the previous week. Four deaths from violence and four inquest cases were registered; and 72, or 38.1 per cent., of the deaths occurred in public institutions. The causes of ten, or 5.3 per cent., of the deaths registered during the week were not certified; the percentage of uncertified deaths in the week under notice was equal to 5.7 in Edinburgh, while all the deaths were duly certified in London. The 156 deaths registered in Belfast during the week ending March 16th included 20 deaths certified as due to cerebro-spinal meningitis or cerebro-spinal fever.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

THE following appointments are notified:—Fleet Surgeon T. O. Meikle to the *Natal* on commissioning. Staff-Surgeons: J. E. H. Phillips to the *Victory*, additional, to be lent to Haslar Hospital, temporary; F. C. B. Gittings to the *Natal*, on commissioning. Surgeons: G. O. Cross to the *Wildfire*, additional, for Sheerness Yard; A. D. Spalding to

the *Wildfire*, additional, for the *Kadylion*; O. E. C. Stanford to the *Argonaut*, and on recommissioning; G. L. Buckridge to the *Victory*, additional, to be lent to Portland Hospital.

Deputy Inspector-General of Hospitals and Fleets Robert Benthall has been placed on the retired list, with permission to assume the rank of Inspector-General of Hospitals and Fleets (dated March 17th, 1907).

ROYAL ARMY MEDICAL CORPS.

Captain G. E. F. Stammers has been selected for duty in connexion with the revision of the manual for the Royal Army Medical Corps.—Captain C. E. Fleming, from the Dublin district, has been posted to the Cork district for duty at Templemore, and Lieutenant-Colonel T. F. MacNeece from Cork has been selected for appointment as an Administrative Medical Officer at Coatham.—Lieutenant-Colonel F. Eckersley and Lieutenant-Colonel C. L. Jesling have joined the London district for duty.

Lieutenant-Colonel George Scott retires on retired pay (dated March 20th, 1907).

Lieutenant-Colonel William Dugdale retires on retired pay (dated March 16th, 1907).

INDIAN MEDICAL SERVICE.

The King has also approved of the retirement from the service of the undermentioned officers:—Lieutenant-Colonel Edward Pettigall Youngerman (dated March 2nd, 1907) and Captain Hugh Birby Lard (dated March 15th, 1907).

VOLUNTEER OFFICERS' DECORATION.

The King has conferred the Volunteer Officers' Decoration upon the undermentioned officers of the Volunteer Force, who have been duly recommended for the same under the terms of the Royal Warrant dated July 25th, 1892:—

Southern Command (Rifle): 2nd Volunteer Battalion the Duke of Cornwall's Light Infantry: Surgeon-Major and Honorary Surgeon-Lieutenant Colonel William Nettle.

Eastern Command (Medical Corps): Royal Army Medical Corps (Volunteers), Sussex and Kent Bearer Company: Lieutenant-Colonel James Turton (Brigadier-Surgeon-Lieutenant-Colonel, Senior Medical Officer, Sussex and Kent Volunteer Infantry Brigade).

Western Command (Rifle): 5th Volunteer Battalion the Cheshire Regiment: Surgeon-Major Charles Averill. 2nd Volunteer Battalion the Welsh Regiment: Surgeon-Lieutenant-Colonel David Hepburn.

Scottish Command (Rifle): 4th (Donside Highland) Volunteer Battalion the Gordon Highlanders: Surgeon-Major Alexander Nicol.

London District (Medical Corps): Royal Army Medical Corps (Volunteers); London District, London Companies: Lieutenant-Colonel and Honorary Colonel Valentine Matthews.

DEATHS IN THE SERVICES.

Surgeon-General Sir John Harry Ker Jones, K.C.B., A.M.D. (retired), at his residence in Florence on March 12th. He entered the Medical Department of the Army in 1842 and in 1854, his regiment being then in India, he went to the Crimea as a volunteer and took part in the attack on the Redan. He served in India during the Sepoy revolt, when he was wounded. He was present at the storming of the heights before Delhi and at the capture of that city. As principal medical officer he went through the Rohilkund campaign and during the Franco-German war he acted as British Medical Commissioner on the staff of the Crown Prince of Prussia, for which services he received from the Emperor the Steel War Medal and Iron Cross. He was principal medical officer of the Afghan campaign in 1878-79. He retired in 1880. We hope to publish an obituary notice of this distinguished officer in an early issue.

THE ARMY ESTIMATES.

The *Broad Arrow* of last week, in an article analysing the Army Estimates for 1907-C8, contains the following:—

In Vote 2, Medical Establishment, Pay, &c., there is a net decrease of £31,000, there being a reduction in pay of £11,500 in the Army Medical Service, £11,200 for civilian practitioners, £200 for Army Nursing Service, and £2500 for clerks and other subordinates. The cost of medicines is reduced by £1000 and miscellaneous appropriations in aid by £100, the only increase shown being £200 for the expenses of the Royal Army Medical College, in which the commandant and some of the professors have been awarded an increase of pay.

ENTERIC FEVER AT FLEETWOOD.

The *Standard* of March 19th contains the following:—
“The Secretary of State for War has forwarded to the

Fleetwood urban council a communication in which he refuses to allow the publication of the official report on the outbreak of enteric fever at Fleetwood Camp, by which two officers lost their lives last summer. Mr. Haldane has, however, followed this communication by a telegram, in which it is stated that the cause of the outbreak was due to the presence in the officers' mess of an unsuspected case of enteric fever in the person of a civilian waiter, named Joyce. It is expected that an animated discussion on the subject will take place at the next council meeting. It will be remembered that the affair caused a considerable sensation in Lancashire last August. Two officers of the 3rd Battalion Loyal North Lancashire Regiment succumbed to the disease and it was freely hinted that the water-supply of Fleetwood was contaminated. This insinuation the local council hotly denied, asserting that their supply was amongst the finest in England, and that if there was any defect in the supply at the camp it was the fault of the War Office authorities and not of the urban council.”

Correspondence.

“Aut alteram partem.”

CASTING UP ACCOUNTS IN CONNEXION WITH MALARIA.

To the Editors of THE LANCET.

SIRS,—It will be my duty in the autumn of this year to present a report to the International Congress of Hygiene at Berlin on the progress of anti-malaria measures in British possessions and, if possible, in America. Ten years will then have elapsed from the date when the parasites of malaria were first discovered in gnats; and I should therefore like to give as complete and trustworthy an account as possible of all that has been done against the disease during that period. From official publications, articles in the medical press, and private letters, I gather that campaigns have been at least commenced in the following localities: Freetown, Lagos, Gambia, Gold Coast, Hong-Kong, Federated Malay States, Admans, Cardia, Khartoum, Trincomalee, Port Said, Natal, Milan Mir, Peshawar, Rawalpindi, Sialkote, Ferozepore, Karachi, Mhow, Kampti, Deesa, Sagar, Jhansi, Poona, Meerut, Lucknow, Secunderabad, Mandalay, Maymyo, all in British dominions; and in Italy, German possessions, Greece, Havana, Panama, and United States. Unfortunately, the available descriptions of the work done and the results obtained in most of these localities are so vague that they are of little value. Will you, therefore, allow me to appeal through your columns to all medical men and sanitary officers who have interested themselves in the campaign to send me the necessary details to the address given below? The statements should, of course, give the area and population of the district dealt with (including towns, villages, plantations, factories, mines, railways, and ships); the exact nature of the protective measures; and, if possible, any facts bearing on their results. In using the information I will, of course, always take care to give the name of my informant, unless specially desired not to do so.

I am, Sirs, yours faithfully,

RONALD ROSS,

Professor of Tropical Medicine, the University, Liverpool.

March 15th, 1907.

THE TRUE AIM OF MEDICAL EDUCATION.

To the Editors of THE LANCET.

SIRS,—In his address on the True Aim of Medical Education before the Hunterian Society Dr. Lauriston Shaw most ably and powerfully states the case against examinations, both as tests of true knowledge and as incentives to learning. So completely has he handled his subject that there appears nothing else to be said against our present system and little else in favour of that he advocates. Yet, when one carefully studies what Dr. Shaw has said one hardly feels some of his arguments to be altogether convincing. In the world as at present constituted one has in matters of all kinds to choose between two sets of views each compounded of obvious good

and obvious evil. In the subject under discussion it remains for us to weigh the good and the evil of each separate system, and having done so, before coming to a conclusion, further to see how far in each case the evil can be reduced to the minimum.

Dr. Shaw deserves great credit, we must all admit, in exposing the flaws in the present system of examinations, but personally I cannot see why the system itself should not be reformed so as to make examinations, as far as humanly possible, true tests of knowledge. There is no reason surely why the subjects of the medical curriculum should offer to an examiner an insuperable difficulty in testing a candidate's real knowledge. Viewing the subjects demanded of the student I should have thought the direct contrary to be the case. With examinations properly conducted I cannot see how they can "exert a demoralising effect upon both parties engaged in teaching"; if that, however, be the case at present, reorganisation should meet the difficulty. Dr. Shaw's arguments seem to me entirely to bear against some of the present details of examinations and not against the system itself. The external system of examination is condemned by Dr. Shaw, but here again his attack is not really on the system but on the defective way it is carried out. For he refers to "the ability to keep one's store of facts on the surface and to pour them out speedily in the presence of a stranger—the power which is essentially created by the crammer, a mixture indeed of memory and cheek." The fault here surely lies with the examiner, possibly with the curriculum, but certainly not with the system. An examiner blessed with ordinary intelligence ought surely to be able to detect superficiality. Most of us, less intellectually endowed, do so every day of our lives. Dr. Shaw's explanation of the growth of the examination system during the last half of the nineteenth century is excellent, so excellent, in fact, that it behoves us to hesitate long before we destroy that system. The Briton, he says, loves fairplay and hates patronage; examinations came into general use to lessen the moral harm of nepotism. Now, before dismissing this objection as out of date, Dr. Shaw will have to convince us that human nature has changed for the better.

Dr. Shaw points out how hospital resident appointments are given by selection and how futile it would be to grant them by competitive examination. True enough; but one must bear in mind that the qualities required in a hospital resident obviously are not merely professional and could not be gauged by an examination test. Professors at universities he instances as not selected by examination, but as these are chosen for special work or special teaching, in which they are eminent, it hardly seems to me that the parallel with the examination of a student holds. The ground-work of the medical sciences, if studied apart altogether from examinations, is vast and requires most of a young man's time. Would it not be a mistake to put the student on to research work before he was properly grounded? Though admittedly the educational effect of the former might be greater in the sense that Matthew Arnold uses the word "education," the product would, I think, tend to be superstructure without a foundation.

I am, Sirs, yours faithfully,

Croydon, March 2nd, 1907.

A. PERCY ALLAN.

To the Editors of THE LANCET.

SIRS,—In his address before the Hunterian Society on Feb. 15th, as published in THE LANCET of March 2nd, Dr. Lauriston E. Shaw draws attention to the evils of the present examination system in medical education. With your permission I should like to bring forward one or two points, not new it will be said, which in my opinion must tend to uphold the present evils.

A registrable qualification can be obtained by passing the examinations of any one of 15 universities, three conjoint boards, and two apothecaries' societies, all doubtless claiming advantages of their own. Now, in my humble opinion, the practice of medicine is of the nature of a public service, and therefore so many means of entrance are undesirable, being liable to give rise to too great variation in the standard of qualification and unnecessary distinctions by the public as to relative values of the qualifications to the detriment of some of the holders. Within the ranks of the profession itself the obtaining of many qualifications (of the nature of vain repetitions) is encouraged by the fact that institution appointments in the majority of cases are given to those who can show the

largest number of combinations of the letters of the alphabet. These are not necessarily indicative of more than an aptitude for retaining series of assorted facts together with a speculative verbosity regarding theories, whilst power of application of knowledge in a practical manner is wholly wanting. Dr. Shaw mentions the lack of desire for these brilliant stars as house officers on the part of some surgeons who are examiners. The holder of an ordinary qualification, such as the Conjoint diploma, whatever his personal qualities may be, is ineligible for the higher posts in institutions except of very humble order, and may from lack of time or means, after holding a resident appointment, be unable to attempt further examinations. He must therefore go into general practice, and may as well stop there; for if later he should see his way to return to the examination arena and obtain another qualification, having got out of the run he stands a poor chance of a senior post at a hospital.

Although his diploma states that he is licensed to practise medicine, midwifery, and surgery, in actual fact he is limited in scope, for it is useless to take up any part of his work specially, as he can only attain the rank of a clinical assistant and remain a feeder to those of many letters on the full staff of the hospitals. Should he have boldness and confidence in himself and dare to perform operations on his trusting patients, I have heard the remark, "What right has he to operate? he is not on a hospital."

To remedy the present state of affairs is probably no light undertaking, but much will be done by destroying the many-portal system and replacing it by a single body which alone has power to grant qualifications. Thus the General Medical Council might be developed into a Government department, regulating, as it does now, the education of the students at the recognised schools and allowing the periodical examinations to be conducted by the teachers. At the end of the prescribed course of study, subject to the production of satisfactory school certificates, the students would be examined for qualification by a board of examiners specially appointed by the department. One qualification only should be granted—namely, doctor of medicine, any candidates who had particularly distinguished themselves being M.D. with honours.

Until some such simplification of the method of qualification is adopted students must suffer from over-examination by the rival bodies and members of the profession be injured by inequalities not always just.

I am, Sirs, yours faithfully,

March 16th, 1907.

A DESIRER OF REFORM.

THE SACCOLAR THEORY OF HERNIA.

To the Editors of THE LANCET.

SIRS,—Mr. R. Hamilton Russell in THE LANCET of March 9th, 1907, p. 683, is right in assuming that "there is at least one sentence in my recent paper with which Dr. Keith will, I know, cordially agree. The saccolar theory will fall or prevail as it is false or true." To that sentence at least of his last letter I can give a full and unreserved assent; it was just that truth might prevail that I ventured to point out that the two fundamental assertions on which he had based his saccolar theory of hernia were without foundation in fact. These two assertions were (1) that there is a diverticulum of peritoneum within the developing bud of the hind limb, which provides a congenital sac for femoral hernia; and (2) that the processus vaginalis may assume during development irregular and multilocular forms, thus furnishing the sacs of the many irregular varieties of inguinal hernia. Perhaps my manner of nailing these to the "counter" was more vigorous than polite or courteous, yet it seemed to me then, as it seems to me now, that the essential thing was that they should be fixed there firmly until Mr. Russell had proved their "face" value. He does not allude to them in his last letter; I conclude, therefore, he agrees with me as to their non-validity. Another reason for my entering into a public criticism of Mr. Russell's theory was that I think the time has come to protest against a current habit on the part of medical men of assigning to "the congenital" all inexplicable conditions of disease. The saccolar theory of hernia is a case in point; because hernial sacs manifest uncommon forms and occupy unusual sites they are assumed to be of congenital origin; it is just as difficult to conceive their manner of formation before birth as after birth. More

often than not we use the word "congenital" to mask our ignorance of the real cause.

In the letters of Mr. Edward Deaneley and Mr. R. W. Murray in *THE LANCET* of Nov. 24th, 1906, p. 1470, and of Mr. Hamilton Russell in your issue of March 9th, 1907, p. 683, we have, I conclude, a full statement of all the facts on which the saccular theory of hernia is based. Concerning these facts all three writers are unanimous. Briefly stated they are: 1. Complete removal of the hernial sac (with, of course, replacement of its contents) works a cure quite as effectively as removal of the sac with suture of the belly wall. They infer, therefore, that it is the presence of a peritoneal sac, not of a lacuna or weakness in the belly wall, which constitutes the essential condition necessary for the formation of a hernia. The sac is not brought down by the hernia; it must therefore be of congenital origin. 2. That the sac, which is usually regarded as of post-natal origin, is similar in form to that which is known to be of prenatal origin; all are therefore of prenatal origin. Further, the shape of the sac is often such that it can only be accounted for by supposing that it is of prenatal origin. On these two grounds is based the saccular theory of hernia. As to the first point: I am quite prepared to believe that the supporters of the saccular theory obtain, as they maintain they do, quite as good results by a complete removal of the sac as those who not only remove the sac but also repair the abdominal wall by operations such as those of Macewen or Basini. But it is not necessary for me to point out that those who merely remove the sac really do much more than remove the sac; by their operation they necessarily set up a reparative inflammatory process along the hernial tract which probably leads to a more effective repair of the belly wall with less destruction of its muscular mechanism than the wiring and suturing employed in more radical operations. It is one thing to admit the success of their method of treatment; it is quite another matter to infer from it that hernial sacs are of prenatal origin. As to the second point: the supporters of the saccular theory, on what grounds I cannot conceive, have concluded that the shape of the hernial sac indicates a prenatal origin. We only know of two diverticula of the peritoneum which are formed before birth—namely, the processus vaginalis and one which frequently occurs at the umbilicus. In no instance have these diverticula been seen of an irregular or of a saccular form; a prenatal diverticulum of the peritoneum in the shape of a hernial sac is unknown; so far as its shape goes, then, it indicates a post-natal development for hernial sacs. Everyone will admit that a hernial sac which is freely continuous with the tunica vaginalis, or one that is connected with the tunica by a patent or fibrous funicular process which is decidedly shorter than the inguinal canal, must be of prenatal origin; but these are the only two forms which can be recognised with certainty as such. So far as I can learn the supporters of the saccular theory have not troubled to seek to distinguish such forms from others.

Having now dealt with the slender evidence they have brought forward in support of their theory I now proceed to bring forward a few details which have escaped their consideration. Since all hernial sacs are pre-formed, why is it that the inguinal sacs fill so readily in the first few years of life, while the femoral sacs do not fill until puberty is reached? Out of 500 consecutive cases of hernia, Mr. Jonathan Hutchinson, junior, found that the inguinal occurred to the femoral form as 3 to 1; Mr. Murray estimates their ratio as 6 to 1; yet in 360 cases of hernia in children Stiles found only one case of femoral hernia—in a girl, aged eight years; in 1424 cases of hernia in children Bull and Coley found only 35 cases of femoral hernia. On the theory that hernia is the result of a high abdominal pressure acting on a weak part of the abdominal wall, I can explain those figures, but I should very much like to know the explanation offered of them by those who hold that all hernial sacs are of congenital origin.

Mr. Deaneley has asked me the question, Why is it, since we all possess weak points in our belly wall and have our abdominal viscera subjected to a high pressure, that we do not all suffer from hernia? In that Mr. Deaneley is in error. We do not all—most fortunately very few of us do—possess any point in our belly wall that cannot resist a pressure much higher than it ever has to bear, even in the stress of a labourer's life. In return I should like to put a question to Mr. Deaneley, Why is it that 50 per cent. of children

under four months of age do not suffer from inguinal hernia? He himself has quoted the result of Sach's observations—namely, that the funicular process was found patent in 59 per cent. of inguinal canals examined in children under four months of age. They have the pre-formed sacs; why do they not have the hernia? Hernia is very common during the first year of life, but is this due to the fact that there is a process of patent peritoneum in the inguinal canal? Is it not rather due to the fact that there is a patency or gap in the resisting structures of the belly wall, which the presence of the open diverticulum necessitates? When he argues that the sac is the cause of hernia he forgets that there cannot be a sac unless there be also an opening in the belly wall for the mouth of that sac.
